This is the female erectile structure homologous to the penis. It consists of a glans, a body, and two crura. The glans contains many nerve endings and is covered by a mucous membrane. The body measures approximately 2 cm and is connected to the pubic ramus by the crura.

VAGINAL VESTIBULE

This is the area between the two labia minora. It is bounded laterally by the line of Hart and medially by the hymenal ring. The Hart line demarcates changes in epithelium. Beyond Hart line the stratified squamous epithelium has a thin keratin layer. Inside Hart line, the epithelium is nonkeratinized. The vestibule extends from the clitoris anteriorly to the fourchette posteriorly (see Fig. 38-26). It contains the openings of the urethra, vagina, greater vestibular glands (also known as *Bartholin glands*), and Skene glands, which are the largest pair of paraurethral glands. It also contains the numerous openings of the lesser vestibular glands. A shallow vestibular depression known as the *navicular fossa* lies between the vaginal orifice and the fourchette.

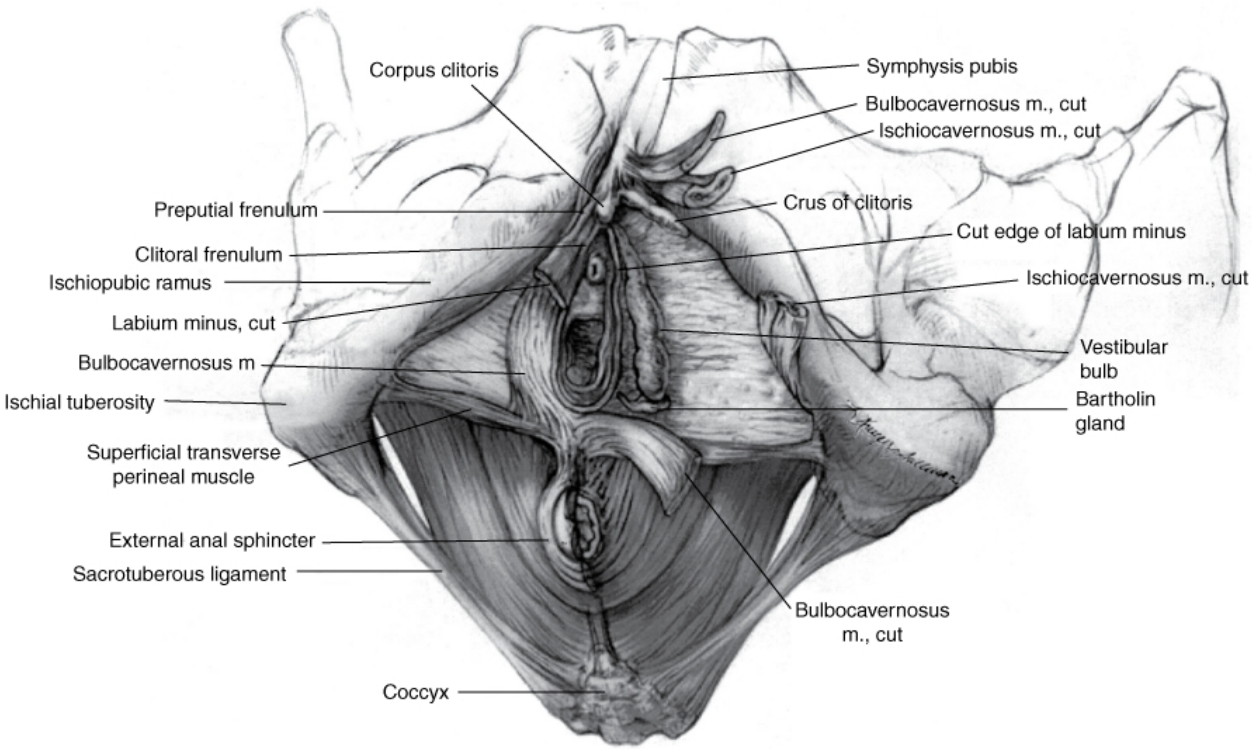
CLINICAL CORRELATION

The Hart line is clinically relevant when choosing incision sites for Bartholin gland duct drainage or marsupialization (see Section 41-6, Bartholin Gland Duct Incision and Drainage). In attempts to recreate near-normal gland duct anatomy following these procedures, incisions placed external to Hart line should be avoided (Kaufman, 1994).

VESTIBULAR BULBS

These are homologues to the male penile bulb and corpus spongiosum. They are two elongate, approximately 3-cm-long, richly vascular erectile masses that surround the vaginal orifice (Fig. 38-27). Their posterior ends are in contact with the Bartholin glands. Their anterior ends are joined to one another and to the clitoris. Their deep surfaces are in contact with the perineal membrane, and their superficial surfaces are partially covered by the bulbocavernosus muscles.

FIGURE 38-27



Source: Schorge JO, Schaffer JI, Halvorson LM, Hoffman BL, Bradshaw KD, Cunningham FG: *Williams Gynecology*: http://www.accessmedicine.com

Perineal structures and superficial perineal space.

Clinical Correlation

The proximity of the Bartholin glands to the vestibular bulbs accounts for the significant bleeding sometimes encountered with Bartholin gland excision (see Section 41-8, Bartholinectomy).

GREATER VESTIBULAR OR BARTHOLIN GLANDS

Also known as Bartholin glands, these are the homologues of the male bulbourethral or Cowper glands. They are in contact with and often overlapped by the posterior ends of the vestibular bulbs (see Fig. 38-27). Each gland is connected to the vestibule by an approximately 2-cm-long duct. The ducts open in the groove between the labia minora and the hymenâ€"the vestibuleâ€"at approximately 5 and 7 o'clock positions.

The glands contain columnar cells that secrete clear or whitish mucus with lubricant properties. These glands are stimulated by sexual arousal. Contraction of the bulbocavernosus muscle, which covers the superficial surface of the gland, stimulates gland secretion.

Clinical Correlation

Obstruction of the Bartholin ducts by proteinaceous material or by inflammation from infection can lead to cysts of variable sizes. An infected cyst can lead to an abscess that is drained surgically. Symptomatic or recurrent cysts may require marsupialization or gland excision (see Sections 41-7, Marsupialization and 41-8, Bartholinectomy).

Perineum

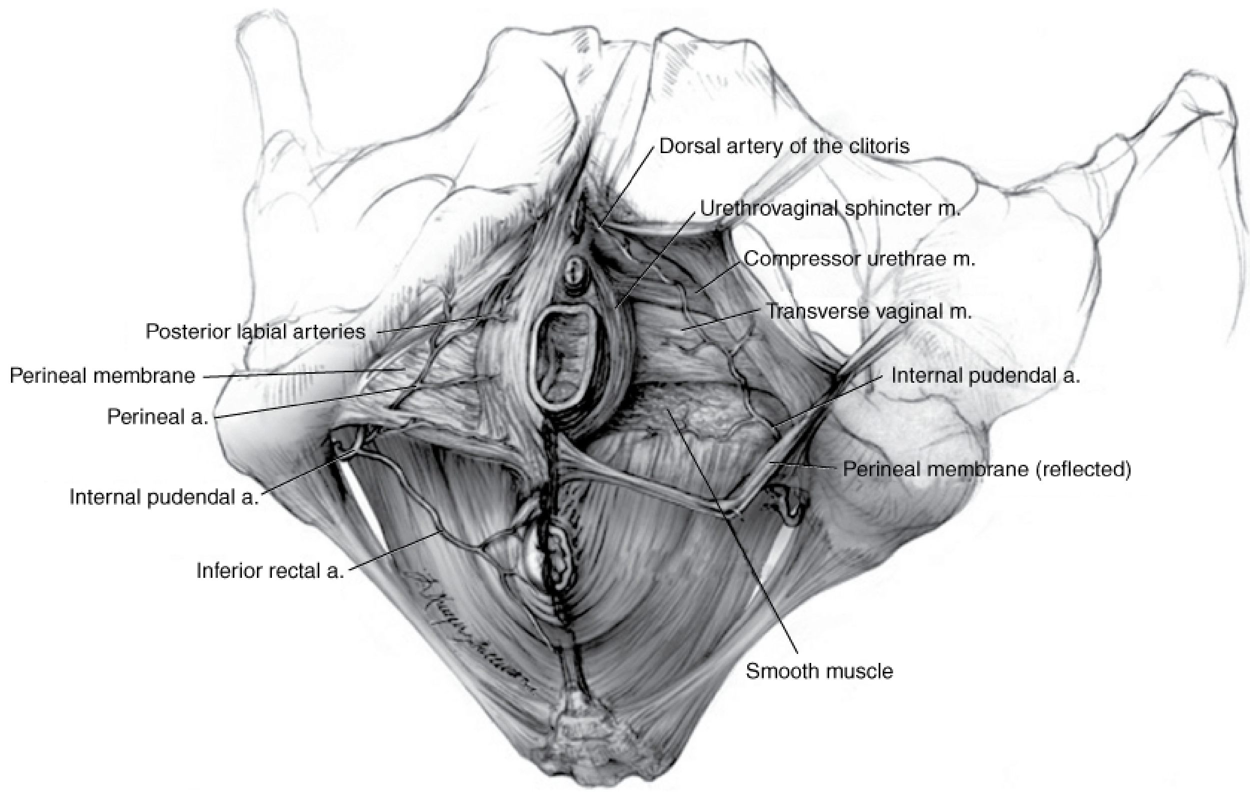
The *perineum* is the diamond-shaped area between the thighs (see Fig. 38-26). It is bounded deeply by the inferior fascia of the pelvic diaphragm and superficially by the skin between the thighs. The anterior, posterior, and lateral boundaries of the perineum are the same as those of the bony pelvic outlet: the pubic symphysis anteriorly, ischiopubic rami and ischial tuberosities anterolaterally, coccyx posteriorly, and sacrotuberous ligaments posterolaterally (see Fig. 38-27). An arbitrary line joining the ischial tuberosities divides the perineum into the anterior or urogenital triangle and a posterior or anal triangle.

ANTERIOR (UROGENITAL) TRIANGLE

As discussed earlier, structures that comprise the vulva or external female genitalia lie in the anterior triangle of the perineum. The base or posterior border of this triangle is the interischial line that usually overlies the superficial transverse perineal muscles (see Fig. 38-27).

The anterior triangle can be further divided into a superficial and a deep pouch or space by the perineal membrane (Fig. 38-28). The superficial perineal space lies below or inferior to the perineal membrane, and the deep space lies above or superior to the membrane.

FIGURE 38-28



Source: Schorge JO, Schaffer JI, Halvorson LM, Hoffman BL, Bradshaw KD, Cunningham FG: *Williams Gynecology*: http://www.accessmedicine.com

Perineal structures found deep to perineal membrane. Not shown is the inferior rectal nerve, which follows the same course as the inferior rectal artery.

Superficial Perineal Space

This space of the anterior triangle is an enclosed compartment that lies between Colles fascia and the perineal membrane. It contains the ischiocavernosus, bulbocavernosus, and superficial transverse perineal muscles; Bartholin glands; vestibular bulbs; clitoris; and branches of the pudendal vessels and nerve (see Figs. 38-8 and 38-27). The urethra and vagina traverse this space.

The *ischiocavernosus muscle* attaches to the medial aspect of the ischial tuberosities posteriorly and the ischiopubic rami laterally. Anteriorly, it attaches to the crus of the clitoris. This muscle may help to maintain clitoral erection by compressing the crus of the clitoris, thus retarding venous drainage.

The *bulbocavernosus muscle* , also termed the *bulbospongiosus muscle,* covers the superficial portion of the vestibular bulbs and Bartholin glands. These muscles attach to the body of the clitoris anteriorly and the perineal body posteriorly. The muscles act to constrict the vaginal lumen, contributing to the release of secretions from Bartholin glands. They also may contribute to clitoral erection by compressing the deep dorsal vein of the clitoris. The bulbocavernosus muscle, along with the ischiocavernosus muscle, acts to pull the clitoris downward.

The *superficial transverse perineal muscles* are narrow strips that attach to the ischial tuberosity laterally and the perineal body medially. They may be attenuated or even absent, but when present, they contribute to the perineal body.

Deep Perineal Space

This pouch lies deep or superior to the perineal membrane (see Fig. 38-28). In contrast to the superficial perineal space, which is a closed compartment, the deep space is continuous superiorly with the pelvic cavity. It contains the compressor urethrae and urethrovaginal sphincter muscles, external urethral sphincter, parts of urethra and vagina, branches of the internal pudendal artery, and the dorsal nerve and vein of the clitoris.

Perineal Membrane

Traditionally, a trilaminar, triangular urogenital diaphragm has been described as the main component of the deep perineal pouch. According to this concept, the urogenital diaphragm consisted of the deep transverse perineal muscles and sphincter urethrae muscles between the perineal membrane (inferior fascia of the urogenital diaphragm) and a superior layer of fascia (superior fascia of the urogenital diaphragm). However, the term *diaphragm* is used to describe a closed compartment. As described earlier, the deep pouch is an open compartment. It is bounded inferiorly by the perineal membrane and extends up into the pelvis (Oelrich, 1980, 1983). As a result, when describing perineal anatomy, the terms *urogenital diaphragm* and *inferior fascia of the urogenital diaphragm* are misnomers and have been replaced by the anatomically correct term *perineal membrane.*

The perineal membrane is a sheet of dense fibrous tissue that spans the opening of the anterior pelvic outlet (see Figs. 38-8 and 38-28). It constitutes the superior boundary of the superficial perineal space, as described earlier. The perineal membrane attaches laterally to the ischiopubic rami, medially to the distal third of the urethra and vagina, and posteriorly to the perineal body. Anteriorly, it attaches to the arcuate ligament of the pubis. In this area the perineal membrane is particularly thick and is referred to as the *pubourethral ligaments.*

Clinical Correlation

The perineal membrane attaches to the lateral walls of the vagina approximately at level of the hymen. It provides support to the distal vagina and urethra by attaching these structures to the bony pelvis.

POSTERIOR (ANAL) TRIANGLE

This triangle contains the ischioanal fossa, anal canal, anal sphincter complex and branches of the internal pudendal vessels and pudendal nerve. It is bounded deeply by the fascia overlying the inferior surface of the levator ani muscles and laterally by the fascia overlying the medial surface of the obturator internus muscles. A splitting of the obturator internus fascia in this area is known as the *pudendal* or *Alcock canal* (see Fig. 38-30). This canal allows passage of the internal pudendal vessels and pudendal nerve before these structures split into terminal branches to supply the structures of the vulva and perineum.

FIGURE 38-30

Nerves of the perineum and external genitalia. *(From Netter, 1989, with permission.)*

Ischiorectal Fossa

The ischioanal or ischiorectal fossa fills the majority of the anal triangle (see Fig. 38-30). It contains adipose tissue and occasional blood vessels. The anal canal and anal sphincter complex lie in the center of this fossa. The ischioanal fossa is bounded superomedially by the inferior fascia of the levator muscles, anterolaterally by the fascia covering the medial surface of the obturator internus muscles and the ischial tuberosities, and posterolaterally by the lower border of the gluteus maximus muscles and sacrotuberous ligaments. At a superficial level, the ischioanal fossa is bounded anteriorly by the superficial transverse perineal muscles. At a superior or deeper level, there is no fascial boundary between the fossa and the tissues deep to the perineal membrane. Posterior to the anus, the contents of the fossa are continuous across the midline except for the attachments of the external anal sphincter fibers to the coccyx. The continuity of the ischioanal fossa across perineal compartments allows fluid, infection, and malignancy to spread from one side of the anal canal to the other, as well as into the perineal compartment deep to

the perineal membrane.

Anal Sphincter Complex

This complex consists of two sphincters and the puborectalis muscle.

External Anal Sphincter

This consists of striated muscle that surrounds the distal anal canal. It consists of a superficial and a deep portion (see Fig. 38-21). The more superficial fibers lie below the internal sphincter and are separated from the anal epithelium only by submucosa. The deep fibers blend with the lowest fibers of the puborectalis muscle. The external sphincter is innervated primarily by the inferior anal branch of the pudendal nerve. The external anal sphincter is responsible for the squeeze pressure of the anal canal (see Chap. 25, Anal Sphincter Complex).

Internal Anal Sphincter

This is the thickening of the circular smooth muscle layer of the anal wall. It is under the control of the autonomic nervous system and is responsible for approximately 80 percent of the resting pressure of the anal canal.

Puborectalis Muscle

This comprises the medial portion of the levator ani muscle that arises on either side from the inner surface of the pubic bones. It passes behind the rectum and forms a sling behind the anorectal junction, contributing to the anorectal angle and possibly to fecal continence (see Figs. 38-9 and 38-21).

PERINEAL BODY

This is a mass of fibromuscular tissue found between the distal part of the posterior vaginal wall and the anus. It is formed by the attachment of several structures. Inferiorly or superficially, the structures that attach to and contribute to the perineal body include the bulbocavernosus, superficial transverse perineal, and external anal sphincter muscles (see Fig. 38-27). Structures that attach at a superior or deeper level are the perineal membrane, levator ani muscles and covering fascia, urethrovaginal sphincter muscles, and distal part of the posterior vaginal wall (see Fig. 38-28). The anterior-to-posterior as well as the superior-to-inferior extents of the perineal body measure approximately 2 to 4 cm.

Clinical Correlation

During episiotomy and other vaginal laceration repairs and with pelvic reconstructive procedures, particular attention should be paid to reconstruction of the perineal body in an effort to prevent pelvic organ prolapse and other pelvic floor dysfunction.

Blood Supply, Lymphatics, and Innervation

The vulva and perineum and their contained structures have an intricate of blood, lymphatic, and nerve supply. Within these patterns, a number of anatomic variants are found.

BLOOD VESSELS

The *external pudendal artery* is a branch of the femoral artery and supplies the skin and subcutaneous tissue of the mons pubis (see Figs. 38-3 and 38-4). The *internal pudendal artery* is one of the terminal branches of the internal iliac artery (see Fig. 38-28). It has a long course from its origin, and the association of this vessel with other structures has clinical importance. It exits the pelvis through the greater sciatic foramen, passes behind the ischial spines, and reenters the perineum through the lesser sciatic foramen. It then has a variable course, usually 2 to 3 cm, through the pudendal or Alcock canal and then divides into terminal branches. These are the *inferior rectal* , *perineal* , and *clitoral arteries* . Branches to the perineum sometimes arise from the pudendal artery before it exits the pelvisâ€”these vessels are called *accessory pudendal arteries.* Other accessory vessels also may arise directly from the anterior or posterior division of the internal iliac artery.

The veins that drain the structures of the vulva and perineum have similar courses and names as the arteries. Venous blood from the vestibular bulbs and other structures, with the exception of the erectile tissue of the clitoris, drains into the internal pudendal veins. The erectile tissue drains into the dorsal vein of the clitoris (see Fig. 38-25). This vein courses backwards into the pelvis and

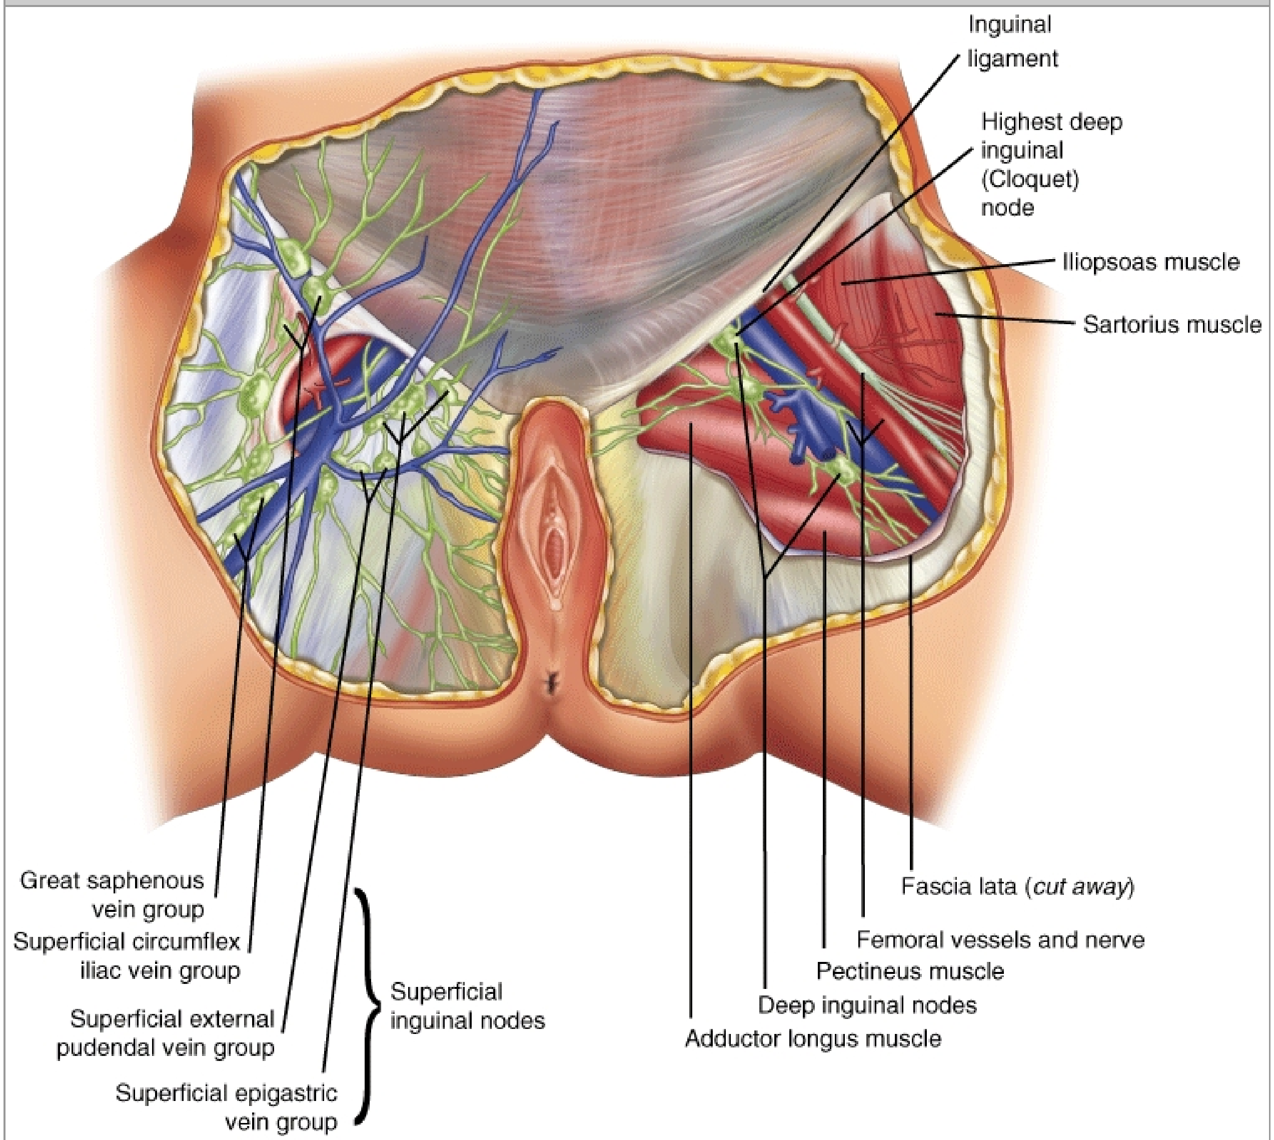
terminates in the periurethral-perivesical venous plexus.

The venous plexus that drains the rectum and anal canal empties into the superior, middle, and inferior rectal veins. The *superior rectal vein* drains into the inferior mesenteric vein, a tributary of the portal vein. The *middle rectal vein* drains into the internal iliac vein. The *inferior rectal vein* drains into the internal pudendal vein and then the internal iliac vein.

LYMPHATIC DRAINAGE

Structures of the vulva and perineum drain into the inguinal lymph nodes, which are located below the inguinal ligament in the upper anterior and medial thigh (Fig. 38-29). There are 10 to 20 inguinal nodes that are divided into a superficial and a deep group. *Superficial inguinal lymph nodes* are more numerous. They are found in the membranous layer of the subcutaneous tissue of the anterior thigh, just superficial to the fascia lata.

FIGURE 38-29



Source: Schorge JO, Schaffer JI, Halvorson LM, Hoffman BL, Bradshaw KD, Cunningham FG: *Williams Gynecology*: http://www.accessmedicine.com

Superficial inguinal lymph nodes and contents of the femoral triangle. *(From Netter, 1989, with permission.)*

The *deep inguinal nodes* vary from one to three in number and are located deep to the fascia lata in the *femoral triangle* . This triangle is bordered superiorly by the inguinal ligament, laterally by the medial border of the sartorius muscle, and medially by the medial border of the adductor longus muscle. The iliopsoas and pectineus muscles form its floor. Within this triangle, the deep nodes are in the *femoral canal* â€"the space that lies on the medial side of the femoral vein. This canal can communicate with the abdominal cavity through the *femoral ring* . Within the femoral triangle, lateral to medial, the structures found in this space are the femoral nerve, artery, vein, and deep inguinal lymphatics in the femoral canal.

The *fossa ovalis* , or saphenous opening, is an opening in the fascia lata and allows communication of superficial with deep inguinal nodes. When there are three deep inguinal nodes, the highest oneâ€"the Cloquet nodeâ€"is located in the lateral part of the femoral ring. From the deep inguinal nodes, efferent channels pass through the femoral canal and femoral ring to the external iliac nodes (see Fig. 33-2). Lymphatics from the skin of the labia, clitoris, and remainder of the perineum drain into the superficial inguinal nodes. The glans and corpora cavernosa of the clitoris may drain directly to the deep inguinal nodes.

INNERVATION

Somatic Innervation

Branches of the pudendal nerveâ€"inferior anal, perineal, and dorsal nerve of the clitorisâ€"provide sensory and motor innervation to the perineum (Fig. 38-30). The *pudendal nerve* is a branch of the sacral plexus and is formed by the anterior rami of the second through the fourth sacral nerve roots. It has a course and distribution similar to the internal pudendal artery.

Visceral Innervation

Clitoral erection requires parasympathetic visceral efferents derived from the pelvic plexus nerves or nervi erigentes. These arise from the second to the fourth sacral spinal cord segments. They reach the perineum along the urethra and vagina, passing through the urogenital hiatus. Sympathetic fibers reach the perineum with the pudendal nerve.

PERIOPERATIVE CONSIDERATIONS: INTRODUCTION

Each year, over 30 million surgical procedures are performed. During these, nearly 1 million patients suffer a postoperative complication (Mangano, 2004). As surgeons, gynecologists assume responsibility for assessing a patient's clinical status to identify modifiable risk factors and prevent perioperative morbidity. However, clinicians also should be prepared to diagnose and manage such complications if they arise.

PREOPERATIVE PATIENT EVALUATION

A properly performed preoperative evaluation serves two important functions. It uncovers comorbidities that require further evaluation and optimization to avert perioperative complications. Second, evaluation allows improved use of operating room resources through increased efficiency (Correll, 2006; Roizen, 2000).

Medical Consultation

Often, a thorough preoperative history and physical examination will reveal poorly controlled or previously undiagnosed disease that would benefit from consultation by an internist. The purpose of a preoperative internal medicine consultation is not to obtain "medical clearance", but rather to provide a risk assessment of a woman's current medical state. During consultation, a summary of the surgical illness should be provided, and clear questions are posed to the consultant (Eagle, 2002; Goldman, 1983). In addition, a complete history and physical examination and prior medical records that report previously performed diagnostic testing should be available to the consulting physician. This usually will prevent unnecessary surgical delays due to redundant testing.

Pulmonary Evaluation

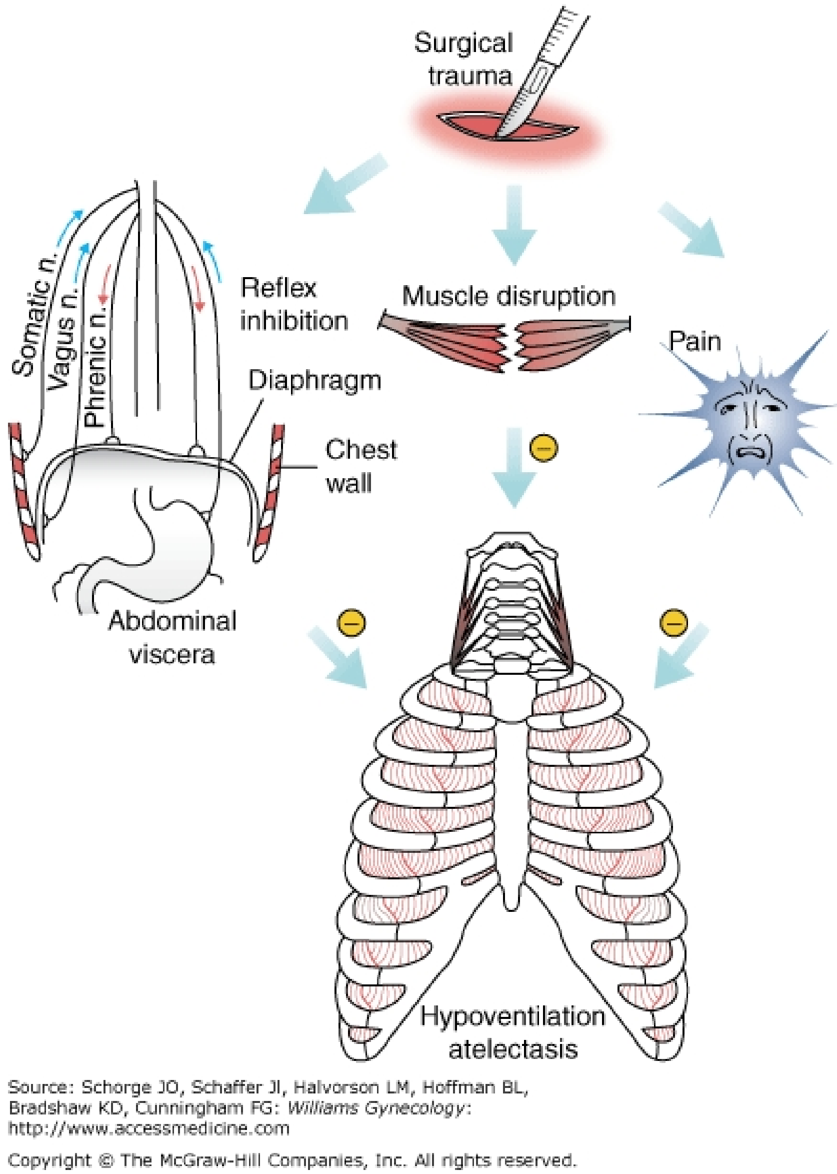
Most postoperative pulmonary morbidity includes atelectasis, pneumonia, and exacerbation of chronic lung diseases.

RISK FACTORS FOR PULMONARY COMPLICATIONS

Procedure-Related Factors

Risk factors for pulmonary complications fall into one of two major categoriesâ€"procedure-related and patient-related. Of these, procedure-related risk factors remain the most important predictors of postoperative complications (Smetana, 1999). For example, upper abdominal incisions as they approach the diaphragm can alter pulmonary function through three mechanisms, as shown in Figure 39-1. As a result, poor diaphragmatic descent postoperatively may result from neurologic, functional, or voluntary disruption during surgery. Poor function may produce persistent decreases in vital capacity and in functional residual capacity and thus predispose patients to atelectasis (Warner, 2000). Surgery duration is another procedure-associated factor. Procedures in which patients receive general anesthesia for longer than 3 hours nearly double the risk of developing a postoperative pulmonary complication. Finally, emergency surgery remains a significant independent predictor of postoperative pulmonary complications. Although these procedure-related risk factors are largely unmodifiable, an appreciation of their associated sequelae should prompt increased postoperative vigilance.

FIGURE 39-1



Surgical factors producing respiratory muscle dysfunction. First, surgical trauma stimulates central nervous system reflexes mediated by both visceral and somatic nerves. These reflexes can inhibit the phrenic nerve. Secondly, muscle disruption impairs respiratory muscle action. Lastly, pain can limit use of respiratory muscles. These factors can reduce lung volumes and produce hypoventilation and atelectasis.

Age

Individuals older than 60 years are at increased risk for developing postoperative pulmonary complications. After stratifying patients for comorbidities, those between 60 and 69 years have a twofold increased, risk. In those older than 70 years, risk is increased threefold (Qaseem, 2006). Baseline cognition should be documented and postoperative sensorium should be monitored because changes may be an early indicator of pulmonary function compromise following surgery.

Smoking

A greater than 20-pack-year smoking history confers a high incidence of postoperative pulmonary complications. Fortunately, this risk can be reduced with smoking abstinence before surgery. Specifically, in preparation for elective surgery, smoking cessation for at least 4 to 8 weeks offers risk reduction (Warner, 1984). Short-term benefits may be related to reduced nicotine and

carboxyhemoglobin levels, improved mucociliary function, decreased upper airway hypersensitivity, and improved wound healing (Moller, 2002; Nakagawa, 2001). Patients with a 6-month or greater history of smoking cessation have complication risks similar to those who have never smoked.

Obesity

Decreases in chest wall compliance and in functional residual capacity predispose morbidly obese patients to intra- and postoperative atelectasis (Zerah, 1993). Eichenberger and colleagues (2002) observed that pulmonary changes in these patients may persist for over 24 hours and require aggressive postoperative lung expansion modalities.

Asthma

Well-controlled asthma is not a risk factor for postoperative pulmonary complications. Warner and coworkers (1996) reported that rates of bronchospasm were less than 2 percent in asthmatic patients.

American Society of Anesthesiologist (ASA) Classification

Although this classification was created to help predict perioperative mortality, it also has been shown to assess risks for cardiovascular and pulmonary complications (Wolters, 1996). Table 39-1 summarizes the American Society of Anesthesiologist (ASA) classification and associated rates of postoperative pulmonary complications (Qaseem, 2006).

Table 39-1 American Society of Anesthesiologists (ASA) Classification

ASA Class	Class Definition	Rates of PPCs by Class (%)
I	A normally healthy patient	1.2
II	A patient with mild systemic disease	5.4
III	A patient with systemic disease that is not incapacitating	11.4
IV	A patient with an incapacitating systemic disease that is a constant threat to life	10.9
V	A moribund patient who is not expected to survive for 24 hours with or without operation	NA

NA = not applicable; PPCs = postoperative pulmonary complications.

From Qaseem, 2006, with permission.

HISTORY AND PHYSICAL EXAMINATION

Elements in a pulmonary review of systems that may serve as harbingers of underlying disease include poor exercise tolerance, chronic cough, and otherwise unexplained dyspnea (Smetana, 1999). Physical examination findings of decreased breath sounds, dullness to percussion, rales, wheezes, rhonchi, and a prolonged expiratory phase may signify a nearly sixfold increase in pulmonary complications (Lawrence, 1996; Straus, 2000).

DIAGNOSTIC TESTING

Pulmonary Function Tests and Chest Radiography

In general, pulmonary function tests (PFTs) offer little information during preoperative pulmonary assessment of patients undergoing nonthoracic procedures. Outside of diagnosing chronic obstructive pulmonary disease (COPD), PFTs are not superior to a through history and physical examination (Lawrence, 1996; Qaseem, 2006). However, if the etiology of symptoms, such as exercise intolerance or dyspnea, remains unclear after clinical examination, then PFTs may provide information that will alter perioperative management.

Routine use of chest radiography to assist in perioperative management remains questionable. Compared with a clinical history and

physical examination, preoperative chest radiographs rarely provide evidence to modify therapy (Archer, 1993).

Serum Albumin and Blood Urea Nitrogen

The National Veterans Administration Surgical Quality Improvement Program reported that serum albumin levels of less than 35 mg/dL were significantly associated with increased perioperative pulmonary morbidity and mortality (Arozullah, 2000). Serum albumin's association with morbidity and mortality may be due to confounding by other comorbidity, and thus, is a marker of malnutrition and disease (Goldwasser, 1997). Likewise, serum blood urea nitrogen (BUN) levels greater than 21 mg/dL similarly correlated, but not to the same degree as serum albumin levels.

PREVENTION OF PULMONARY COMPLICATIONS

Lung Expansion Modalities

Techniques aimed at reducing anticipated postoperative decreases in lung volumes can be simple and include postoperative deep breathing exercises, incentive spirometry, and early ambulation. In conscious and cooperative patients, deep breathing effectively improves lung compliance and gas distribution (Chumillas, 1998; Ferris, 1960; Thomas, 1994). With these exercises, a woman is asked to take five sequential deep breaths every hour while awake and hold each for 5 seconds. An incentive spirometer can be added to assist by providing direct visual feedback of her efforts. In addition to deep breathing, early ambulation can enhance lung expansion as well as provide protection from venous thromboembolism. Meyers and associates (1975) demonstrated an increase in functional residual lung capacity of up to 20 percent simply by maintaining an upright posture. Alternatively, formal respiratory physiotherapy may include: (1) chest physical therapy in the form of percussion, clapping, or vibration; (2) intermittent positive-pressure breathing (IPPB); and (3) continuous positive airway pressure (CPAP).

These simple and more formal prophylactic methods are all effective in preventing postoperative pulmonary morbidity, and no method is superior to another. Thomas and colleagues (1994) performed a meta-analysis to compare incentive spirometry (IS), IPPB, and deep breathing exercises (DBEs). In comparison with no therapy, IS and DBEs are superior in preventing postoperative pulmonary complications, and over 50 percent reductions were observed. In addition, no significant differences were noted when comparing IS with DBEs, IS with IPPB, and DBEs with IPPB (Thomas, 1994). However, chest physical therapy, IPPB, and CPAP are more expensive and labor-intensive (Pasquina, 2006). Accordingly, these methods typically are reserved for patients who are unable to perform simpler effort-dependent therapies.

Nasogastric Decompression

Postoperatively, nasogastric tubes (NGTs) are often placed for gastric decompression. However, nasogastric intubation bypasses normal upper and lower respiratory tract mucosal defenses and exposes patients to risks for nosocomial sinusitis and pneumonia. Routine use of an NGT after surgery is associated with increased cases of pneumonia, atelectasis, and aspiration compared with selective use (only in the case of symptomatic abdominal distention or postoperative nausea and vomiting) (Cheatham, 1995). Accordingly, the choice to implement this drainage method should be balanced against respiratory risks.

Cardiac Evaluation

Cardiovascular disease is the leading cause of death in most industrialized countries and contributes significantly to perioperative mortality in patients undergoing cardiac and noncardiac surgery.

RISK FACTORS FOR CARDIAC COMPLICATIONS

Valvular Heart Disease

Careful chest auscultation will reveal findings suspicious for native valvular lesions. Of the most commonly found defects, aortic stenosis carries the highest independent risk factor for perioperative complications (Kertai, 2004). For other lesions, the degree of heart failure and associated cardiac arrhythmias are the best indicators of risk.

Heart Failure

In patients with a history of congestive heart failure, strategies aim to maximize hemodynamic function and minimize postoperative stress (Eagle, 2002). In addition, judicious use of diuretics usually will avoid intraoperative hypovolemia and related hypotension.

Arrhythmias

These are usually symptoms of underlying cardiopulmonary disease or electrolyte abnormalities. Accordingly, preoperative management should focus on correcting the primary process. However, if pacemakers and implantable cardioverter-defibrillators (ICDs) are required for arrhythmia treatment prior to surgery, they typically are placed for the same indications as in nonoperative circumstances (Gregoratos, 2002).

Hypertension

Except in the setting of systolic blood pressures greater than 180 mm Hg and diastolic blood pressures greater than 110 mm Hg, hypertension is not predictive of perioperative cardiac events and should not postpone surgical intervention (Casadei, 2005; Goldman, 1979; Weksler, 2003). If possible, to lower postoperative cardiac complications related to hypertension, blood pressure should be lowered several months prior to an anticipated procedure (Fleisher, 2002). Avoiding hypo- or hypertension intraoperatively with careful postoperative monitoring is recommended. Importantly, intravascular volume expansion, pain, and agitation may exacerbate postoperative hypertension.

DIAGNOSTIC TESTING AND ALGORITHM

Preoperative guidelines have been developed by several groups to help predict the risk of perioperative cardiac complications. The three most prominent lists used in clinical practice are those jointly developed by the American College of Cardiology and the American Heart Association (ACC/AHA), guidelines published by the American College of Physicians (ACP), and the Revised Cardiac Risk Index (RCRI) (American College of Physicians, 1997; Eagle, 2002; Lee, 1999). Each defines major and minor clinical predictors to help guide clinical decision making and offers specific recommendations.

American College of Cardiology and the American Heart Association Guidelines

First published in 1996 and updated in 2002, the ACC/AHA guidelines represent an extensive review of the literature by 12 committee members from various areas of cardiovascular care. This stepwise strategy centers on assessment of three major considerations: clinical predictors, functional capacity, and surgery-specific risk. In general, for gynecologic surgery, cardiac complication risks are greatest with major emergency procedures and operations associated with large intravascular fluid shifts. In contrast, lowest risks are found with brief endoscopic procedures.

Revised Cardiac Risk Index

The Revised Cardiac Risk Index (RCRI) has been tested extensively and offers accurate estimates of cardiac risk (Lee, 1999). The major difference between the RCRI and the ACC/AHA guidelines is the incorporation of exercise capacity in the ACC/AHA tool. Creators of the RCRI suggest that cardiac risk may be overestimated by a patient's noncardiac limitations in function, such as musculo-skeletal pain. Thus, these investigators place greater emphasis on cardiac and vascular disease markers.

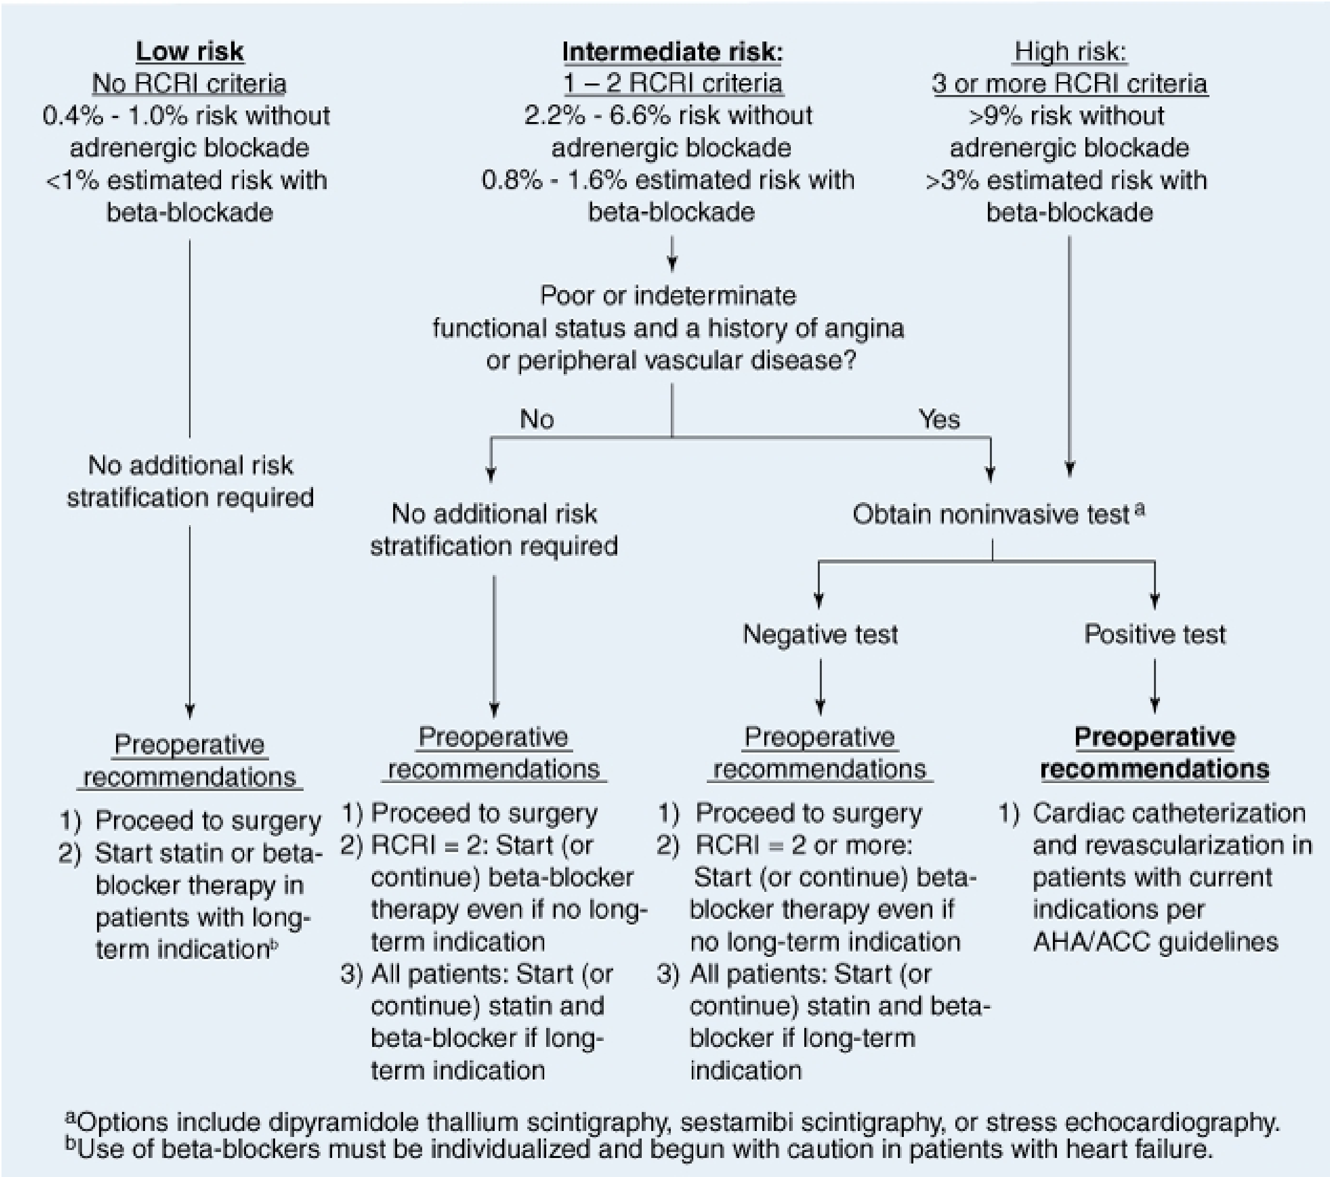
Using the RCRI, an initial evaluation and electrocardiogram (ECG) are completed, and the number of cardiac risk indices from Table 39-2 is calculated. Entry into the algorithm, as shown in Figure 39-2, depends on the number of RCRI criteria (Auerbach, 2006). The use of a dipyramidole thallium scintigraphy, sestamibi scintigraphy, or stress echocardiography as methods of noninvasive cardiac diagnostics should follow ACC/AHA guidelines (Cheitlin, 2003; Falcone, 2003).

Table 39-2 Clinical Factors Important in Assessing Perioperative Cardiac Risk
Revised Cardiac Risk Index (RCRI) Criteria
Patient is at risk if he or she has any one of the following:
• High-risk surgical procedure, defined as thoracic, abdominal, or pelvic vascular (e.g., aorta, renal, mesenteric surgery).
• Ischemic heart disease, defined as: History of myocardial infarction History of/or current angina Use of sublingual nitroglycerin Positive exercise test findings Q waves on ECG Patients who have undergone PTCA or CABG and who have chest pain presumed to be of ischemic origin
• Heart failure, defined as: Left ventricular failure by physical examination History of paroxysmal nocturnal dyspnea History of pulmonary edema S_3 or bilateral rales on physical examination Pulmonary edema on chest radiograph
• Cerebrovascular disease, defined as: History of transient ischemic attack History of cerebrovascular accident
• Insulin-dependent diabetes mellitus
• Chronic renal insufficiency, defined as baseline creatinine ≥ 2.0 mg/dL

CABG = coronary artery bypass graft; ECG = electrocardiogram; PTCA = percutaneous transluminal coronary angioplasty.

From Auerbach, 2006, with permission.

FIGURE 39-2



Algorithm to assess preoperative cardiac risk using Revised Cardiac Risk Index (RCRI) criteria. *(From Auerbach, 2006, with permission.)*

PREVENTION STRATEGIES

Beta-Blocker Drugs

Lindenauer and associates (2005) retrospectively assessed the impact of perioperative beta-blocker use and its effect on in-hospital mortality. In patients with an RCRI of 2 or more, mortality was reduced significantly among patients undergoing major noncardiac procedures who were given beta-blockers perioperatively. Conversely, administration of beta-blockers was potentially harmful in those with low cardiac risk (RCRI of 0 or 1). Outpatient initiation is followed by dosage titration to achieve a resting heart rate of 60 to 65 beats per minute, and therapy is continued for at least 7 days (and ideally 30 days) unless otherwise indicated by pre-existing cardiac disease (Auerbach, 2006; Mukherjee, 2003).

Coronary Revascularization

Diagnostic cardiac catheterization should be considered in high-risk cardiac patients if noninvasive stress testing suggests advanced disease. In such cases, revascularization through coronary artery bypass grafting (CABG) or percutaneous angioplasty offers comparable benefits perioperatively (Hassan, 2001).

Anemia and Cardiac Risk

Anemia has been shown to be an independent risk factor for congestive heart failure (Kannel, 1987). Wu and colleagues (2007) recently found that any degree of hematocrit dysfunction, independent of surgical intervention, increases the risk of postoperative events. They found that the adjusted risk of 30-day postoperative mortality and cardiac morbidity begins to rise when hematocrit levels are above 51 percent and below 39 percent. A study by Silverberg and colleagues (2001) found that correction of even mild anemia (Hgb < 12.5 percent) offered significant improvements in cardiac function. Iron therapy is not a substitution for appropriate cardiac disease treatment, but extrapolated data suggest that maintaining a hemoglobin level above 10 percent is important and reduces perioperative morbidity and mortality.

Hepatic Evaluation

The liver plays a central role in drug metabolism; synthesis of proteins, glucose, and coagulation factors; and excretion of endogenous compounds. Increasing incidences of hepatic disease similarly have increased the number of patients with potential hepatic dysfunction. Accordingly, hepatic function should be assessed if underlying liver disease is suspected.

In patients with suspected liver disease, inquiry should include family histories of jaundice or anemia, recent travel history, exposure to alcohol or other hepatotoxins, and medication use (Patel, 1999). Physical findings suggestive of underlying liver disease include jaundice, scleral icterus, spider angiomas, ascites, hepatomegaly, asterixis, and cachexia.

Of liver diseases, acute and chronic hepatitis are encountered commonly. Postoperative outcome in patients with hepatic disease is primarily determined by the nature and severity of the underlying liver pathology along with the nature of the intended surgical procedure (Sahin, 2007). With acute hepatitis, regardless the cause, there is a high associated perioperative mortality. For this reason, primary management involves supportive care and delay of elective surgical intervention until the acute process has subsided (Patel, 1999). In those with chronic hepatitis, variable levels of hepatic dysfunction are found. Compensated disease carries a low risk of perioperative complications (Sirinek, 1987).

Renal Evaluation

The kidney is involved with excretion of metabolic waste, hematologic processes, and fluid and electrolyte balance. Accordingly, patients with known renal insufficiency should have a serum chemistry panel and complete blood count (CBC) evaluated prior to surgery. Chronic anemia due to renal insufficiency typically will require preoperative administration of erythropoietin or perioperative transfusion. Dialysis patients require intensive pre- and postoperative surveillance for signs of electrolyte abnormalities and fluid overload. Ideally, these patients' volume status and electrolytes (potassium in particular) can be optimized by performing dialysis the day prior to surgery. Additionally, further renal insult is averted by avoiding nephrotoxic agents. Pharmacokinetic consultation may be warranted to adjust other medication dosages because serum levels in these patients may be unpredictable postoperatively.

Hematologic Evaluation

ANEMIA

Preoperative anemia is one of the most common laboratory abnormalities encountered during the preoperative gynecologic surgery evaluation. In the absence of a clear etiology, further evaluation is necessary to correct reversible causes.

The preoperative interview not only should focus on signs of symptomatic anemia (i.e., fatigue, dyspnea with exertion, and palpitations) but also should include identifying risk factors for underlying cardiovascular disease. The physical examination should incorporate thorough pelvic and rectal examinations and stool guaiac testing.

Relevant diagnostic testing for anemic women includes CBC, serum iron level, total iron-binding capacity, ferritin level, reticulocyte

count, and vitamin B_{12} and folate levels. Results from these laboratory studies will dictate preoperative treatment of anemia.

The perioperative decision to transfuse a patient depends in part on the patient's cardiac status. If significant cardiac disease is absent, or if a blood loss of less than 30 percent of total blood volume is anticipated, then an otherwise healthy woman can tolerate a postoperative hemoglobin level of as low as 6 to 7 g/dL (Simon, 1998). A recent randomized controlled trial with patients undergoing elective colorectal surgery found preoperative supplementation of ferrous sulphate 200 mg orally three times daily for 2 weeks significantly reduces the need for postoperative blood transfusions (Lidder, 2007). Conversely, transfusions should be considered if perioperative hypotension and tachycardia fail to respond to volume expansion.

AUTOLOGOUS BLOOD DONATION

Fear of infection from allogenic blood transfusions has lead to the development of autologous transfusion practices. Two of the most popular options include preoperative autologous donation and salvage autologous transfusions, which are discussed in detail in Chapter 40, Fluid Resuscitation and Blood Transfusion (Vanderlinde, 2002).

COAGULOPATHIES

Coagulopathies generally are grouped into two categoriesâ€”inherited and acquired. Disorders involving platelets or clotting factors can be elicited through a careful history and physical examination. A personal history of easy bruising, unexpected amounts of bleeding with minor injury, or lifelong menorrhagia should alert a clinician to the possibility of coagulopathy (see Chap. 8, Coagulopathy). careful review of systems and complete medication list, including herbal preparations, may highlight potential causes. In general, perioperative platelet transfusions typically are required if counts are below 50,000/µL in a patient at risk of bleeding (see Chap. 40, Platelets).

PREOPERATIVE MANAGEMENT OF ORAL ANTICOAGULATION

Women with atrial fibrillation, mechanical heart valves, or recent venous thromboembolism (VTE) are at increase risk for VTE. As a result, these patients typically are prescribed chronic oral warfarin therapy. In addition, surgery inherently increases a patient's risk of developing VTE. Thus, a need for anticoagulation in this group is clear. However this need should be balanced against the risk of bleeding complications from surgery. For these reasons, Kearon and Hirsh (1997) proposed recommendations for the preoperative management of anticoagulants during the period in which the international normalized ratio (INR) is less than 2.0 in patients who use these drugs chronically (Table 39-3).

Table 39-3 Recommendations for Preoperative and Postoperative Anticoagulation in Patients WHO Are Taking Oral Anticoagulants[a]

Indication	Before Surgery	After Surgery
Acute venous thromboembolism		
• Month 1	IV heparin[b]	IV heparin[b]
• Months 2 and 3	No change[c]	IV heparin
Recurrent venous thromboembolism[d]	No change[c]	SC heparin
Acute arterial embolism		
• Month 1	IV heparin	IV heparin[e]
Mechanical heart valve	No change[c]	SC heparin
Nonvalvular atrial fibrillation	No change[c]	SC heparin

[a] IV heparin denotes intravenous heparin at therapeutic doses, and SC heparin denotes subcutaneous unfractionated or low-molecular-weight heparin in doses recommended for prophylaxis against venous thromboembolism in high-risk patients.

[b] A vena caval filter should be considered if acute venous thromboembolism has occurred within 2 weeks or if the risk of bleeding during intravenous heparin therapy is high.

[c] If patients are hospitalized, subcutaneous heparin may be administered, but hospitalization is not recommended solely for this purpose.

[d] The term refers to patients whose last episode of venous thromboembolism occurred more than 3 months before evaluation but who require long-term anticoagulation because of a high risk of recurrence.

[e] Intravenous heparin should be used after surgery only if the risk of bleeding is low.

From Kearon, 1997, with permission.

After an acute VTE, the recurrence risk without anticoagulation is between 40 and 50 percent. However, the risk of recurrent disease drops significantly after 3 months of warfarin therapy (Coon, 1973; Kearon, 1997; Levine, 1995). Specifically, a delay in surgery and continued warfarin therapy for an additional 2 to 3 months drop the recurrence risk to 5 to 10 percent and avoid a need for preoperative heparin (Kearon, 1997; Levine, 1995). Thus, in those with recent VTE, a surgical delay, if feasible, may be advantageous and should be considered.

Following temporary cessation of oral anticoagulation therapy, surgery can be performed safely once the INR reaches 1.5 (Tinker, 1978; White, 1995). If the INR is between 2.0 and 3.0, approximately 4 days are required for the ratio to reach 1.5. After postoperative reinstitution of anticoagulation, approximately 3 days are required to reach therapeutic levels (Harrison, 1997; White, 1995). Importantly, postoperative heparin should not be restarted until at least 12 hours after major surgery and longer if there is evidence of bleeding.

Endocrine Evaluation

The pathophysiologic stress of surgery can exacerbate endocrine conditions such as thyroid dysfunction, diabetes mellitus, and adrenal insufficiency.

HYPERTHYROIDISM AND HYPOTHYROIDISM

Both hyper- and hypothyroidism have anesthetic and metabolic derangements unique to each disease state. Nevertheless, management goals for both aim to achieve a euthyroid state before surgery.

Hyperthyroidism carries the risk of developing thyroid storm perioperatively. Moreover, airway compromise is a risk in those with goiter, and during physical examination, special attention should be given to evaluating for tracheal deviation. In addition to thyroid function tests, an ECG and serum electrolyte levels can help to predict signs of pre-existing metabolic stress. Patients should be encouraged to maintain their usual medications at prescribed dosages until the day of surgery.

Newly diagnosed hypothyroidism generally does not require preoperative therapy except in cases of severe disease with signs of cardiac depression, electrolyte irregularities, and hypoglycemia.

DIABETES MELLITUS

Long-term complications of diabetes mellitus may include vascular, neurologic, cardiac, and renal dysfunction. Thus, a vigilant preoperative risk assessment of these comorbidities in patients with diabetes mellitus is essential. In addition, increased postoperative morbidity has been linked with poor preoperative glycemic control. Specifically, glucose levels of greater than 200 mg/dL and hemoglobin A_{1C} levels of greater than 7 percent are both associated with significantly increased rates of postoperative wound infection (Dronge, 2006; Trick, 2000).

At minimum, diabetic patients undergoing major surgical procedures would benefit from three diagnostic testsâ€”serum electrolyte levels, urinalysis, and an ECGâ€”to screen for metabolic disturbances, undiagnosed nephropathy, and unrecognized cardiac ischemia in the form of abnormal Q waves, respectively.

In general, stress induced by surgery and anesthesia can lead to elevations in catecholamine levels, relative insulin deficiency, and hyperglycemia (Devereaux, 2005). Although glycemic responses may vary with surgery, overt hyperglycemia should be avoided to minimize postoperative complications related to dehydration, electrolyte abnormalities, diminished wound healing, and even ketoacidosis in type I diabetics (Jacober, 1999). However, fluctuations in oral intake and metabolic need make optimal glycemic

control labor-intensive. Moreover, clear evidence for glucose targets are lacking. As a result, most providers aim for glucose readings below 200 g/dL (Table 39-4) (Finney, 2003; Garber, 2004). Table 39-5 and Figure 39-3 summarize perioperative recommendations set forth by Jacober and colleagues (1999) based on disease severity.

Table 39-4 Sliding-Scale Insulin Order Example[a]

Blood Glucose, mmol/L (mg/dL)[b]	Increment Formula	Calculation	Short-Acting Insulin, units
0â€“11.0 (0â€“200)	0	0	0
11.1â€“14.0 (201â€“250)	1 x (TDI/30)	1 x (120/30)	4
14.1â€“17.0 (251â€“300)	2 x (TDI/30)	2 x (120/30)	4
17.1â€“20.0 (301â€“350)	3 x (TDI/30)	3 x (120/30)	12
20.1â€“23.0 (251â€“400)	4 x (TDI/30)	1 x (120/30)	16
23.1â€“26.0 (401â€“450)	5 x (TDI/30)	5 x (120/30)	20
>26.0 (>450)	Call physician	Call physician	Call physician

[a] Example uses a preoperative total daily insulin dose (TDI) of 120 units.

[b] For convenience, conversions of millimoles per liter to milligrams per deciliter are approximate.

From Jacober, 1999, with permission.

Table 39-5 Perioperative Management of Diabetes Mellitus by Disease Type

Disease	Preoperative Management	Postoperative Management
Type 2 DM treated with diet alone	No additional care with PRN subcutaneous regular insulin for AM hyperglycemia	PRN subcutaneous regular insulin
Type 2 DM treated with oral hypoglycemic agents	Discontinue all agents on the day of surgery	Supplemental subcutaneous insulin until return of normal diet, at which time preoperative therapy can be reinstituted
Type 1or 2 DM treated with insulin	See Figure 39-3	Sliding-scale insulin (Table 39-4)

DM = diabetes mellitus.

Perioperative management recommendations for surgical patients with diabetes mellitus. IV = intravenous; MDI = multiple doses of short-acting insulin. *(From Jacober, 1999, with permission.)*

ADRENAL INSUFFICIENCY

Perioperatively, hypotension can result from inadequacy of the hypothalamic-pituitary-adrenal (HPA) axis due to secondary suppression from chronic steroid use. Despite this physiologic understanding, controversy surrounds steroid supplementation during the perioperative period.

Corticosteroid users who undergo minor surgical procedures or who use lower steroid doses (less than 5 mg prednisone per day for no more than 2 weeks within the past year) generally are assumed not to be at risk for adrenal suppression. Therefore, additional steroid therapy is not recommended. However, those taking 5 to 20 mg prednisone per day for more than 3 weeks may be at risk for HPA axis suppression. In these patients, an adrenocorticoticotropic hormone (ACTH) stimulation test can verify adrenal suppression and identify those who may benefit from perioperative steroid supplementation.

The value of perioperative steroid supplementation remains an area of chronic debate (Bromberg, 1991). For example, patients who took at least 7.5 mg prednisone daily for several months with secondary adrenal insufficiency documented by ACTH testing were randomized to placebo versus high-dose cortisol supplementation. Simply continuing the patient's usual daily dose of steroids perioperatively resulted in no increase in hypotension or other perioperative signs of adrenal insufficiency (Glowniak, 1997). If an additional steroid dose is administered, patients should be titrated down to their daily replacement within 48 hours of surgery. Table 39-6 summarizes strategies for steroid supplementation based on surgical stress.

Table 39-6 Guidelines for Adrenal Supplementation Therapy[a]

Medical or Surgical Stress	**Corticosteroid Dosage**
Minor	
Inguinal hernia repair	25 mg hydrocortisone or 5 mg methylprednisolone IV on day of procedure only
Colonoscopy	
Mild febrile illness	
Mildâ€“moderate nausea/vomiting	
Gastroenteritis	
Moderate	
Open cholecystectomy	50â€“75 mg hydrocortisone or 10â€“15 mg methylprednisolone IV on day of procedure Taper quickly over 1â€“2 days to usual dose
Hemicolectomy	
Significant febrile illness	
Pneumonia	
Severe gastroenteritis	
Severe	
Major cardiothoracic surgery	100â€“150 mg hydrocortisone or 20â€“30 mg of methylprednisolone IV on day of procedure Rapid taper to usual dose over next 1â€“2 days
Whipple procedure	
Liver resection	
Pancreatitis	
Critically ill	
Sepsis-induced hypotension or	50â€“100 mg hydrocortisone IV q6â€“8h or 0.18 mg/kg/h as a continuous infusion and 50 µg/d

shock	fludrocortisone until shock resolves May take several days to a week or more Then gradually taper, following vital signs and serum sodium

[a] Patients receiving 5 mg/d or less of prednisone should receive their normal daily replacement but do not require supplementation. Patients who receive greater than 5 mg/d of prednisone should receive the preceding therapy in addition to their maintenance therapy.

From Coursin, 2002, with permission.

DIAGNOSTIC TESTING GUIDELINES

In the absence of a clinical indication, a routine panel of preoperative tests does not enhance the safety or quality of care. Roizen and colleagues (2000) found that nearly half the abnormalities seen on routine preoperative testing were ignored by clinicians. Moreover, multiple studies have documented the inefficiency of hematologic tests to yield clinically significant diagnoses (Kaplan, 1985; Korvin, 1975). Most important, diagnostic testing has not been shown to outperform a clinical history and physical examination (Rucker, 1983). Thus, in the absence of changes in clinical status, diagnostic tests found to be normal 4 to 6 months prior to surgery may be used as "preoperative tests". In patients managed this way, MacPherson and colleagues (1990) found that fewer than 2 percent had significant changes over the course of 4 months.

Pregnancy Exclusion

Pregnancy should be identified prior to surgery. Although many indicated gynecologic procedures may be performed during pregnancy, re-evaluation of the need and the approach to many operations are affected by concurrent pregnancy.

Several preventive steps can avoid procedures in women with early, undiagnosed pregnancies. Providing contraception well in advance of surgery, scheduling surgery in the follicular phase, and preoperative serum beta human chorionic gonadotropin (β-hCG) testing are effective methods to prevent or detect early pregnancy concurrent with surgery (American College of Obstetricians and Gynecologists, 2003).

Pap Smear Screening

As with pregnancy, cervical neoplasia may alter the need or approach to surgical correction of a gynecologic problem. For example, simple (Type 1) hysterectomy performed to treat a benign gynecologic condition will be inadequate treatment to cure most stages of cervical cancer (see Chap. 30, Papanicolaou Smear). Accordingly, women should have current Pap smear screening prior to surgery.

INFORMED CONSENT

Obtaining informed consent is a process and not merely a medical record document (Kondziolka, 2006; Lavelle-Jones, 1993; Nandi, 2000). This conversation between a clinician and patient should enhance the woman's awareness of her diagnosis and contain discussion of medical and surgical care alternatives, procedure goals and limitations, and surgical risks. Written documentation serves as a historical record of the patient's understanding and agreement.

Despite a clinician's recommendations, an informed patient may decline a particular intervention. A woman's decision-making autonomy must be respected, and the clinician should document informed refusal in the medical record. Appropriate documentation should include: (1) the patient's refusal to consent to the recommended intervention, (2) notation that the value of the intervention has been explained to the patient, (3) the patient's reasons for refusal, and (4) a statement describing the health consequences as described to the patient (American College of Obstetricians and Gynecologists, 2004).

SPECIAL CONSIDERATIONS

Surgical Site Infection Prophylaxis

Antibiotic prophylaxis can reduce hospital-acquired infections significantly following gynecologic surgery. Decisions regarding the choice, timing, and duration of antibiotic prophylaxis are guided by the intended procedure and the anticipated organisms to be encountered. Prophylaxis is summarized in Table 39-7 and discussed in Chapter 3, Clean Wounds.

Table 39-7 Antimicrobial Prophylactic Regimens by Procedure

Procedure	Antibiotic	Dose
Vaginal/abdominal hysterectomy[a]	Cefazolin	1- or 2-g single dose IV
	Cefoxitin	2-g single dose IV
	Metronidazole[b]	1-g single dose IV
	Tinidazole[b]	2-g single oral dose (4â€"12 hours before surgery)
Laparoscopy	None	
Laparotomy	None	
Hysteroscopy	None	
Hysterosalpingogram	Doxycycline[c]	100 mg orally twice daily for 5 days
IUD insertion	None	
Endometrial biopsy	None	
Induced abortion/D&C	Doxycycline	100 mg orally 1 hour before procedure and 200 mg orally after procedure
	Metronidazole	500 mg orally twice daily for 5 days
Urodynamic testing	None	

IV = intravenously; IUD = intrauterine device; D&C = dilatation and curettage.

[a] A convenient time to administer antibiotic prophylaxis is just before induction of anesthesia.

[b] Antimicrobial agents of choice in women with a history of immediate hypersensitivity to penicillin.

[c] If hysterosalpingogram demonstrated dilated fallopian tubes. No prophylaxis is indicated for a study without dilated tubes.

From American College of Obstetricians and Gynecologists, 2006, with permission.

Subacute Bacterial Endocarditis Prophylaxis

Sufficient evidence exists regarding the association between bacteremia and postprocedural endocarditis (Durack, 1995; van der Meer, 1992). Despite a lack of randomized trials, prevention of this highly morbid complication with preoperative antibiotics is justified in patients at risk of developing disease (Table 39-8) (Dajani, 1997; Seto, 2007). The mechanism behind the prevention of subacute bacterial endocarditis (SBE) is unclear, but evidence suggests that antibiotics alter bacterial adhesion to heart valves (Moreillon, 1986).

Table 39-8 Subacute Bacterial Endocarditis Prophylaxis by Surgical Procedure

Cardiac Conditions Associated with Endocarditis	**Endocarditis Prophylaxis by Surgical Procedure**
Endocarditis prophylaxis recommended	**Endocarditis prophylaxis recommended**
High-risk category	Gastrointestinal tract[a]
Prosthetic cardiac valves, including bioprosthetic and homograft valves	Surgical operations that involve intestinal mucosa
Previous bacterial endocarditis	Genitourinary tract
Complex cyanotic congenital heart disease (e.g., single-ventricle states, transposition of the great arteries, tetralogy of Fallot)	Cystoscopy
Surgically constructed systemic pulmonary shunts or conduits	Urethral dilation
Moderate-risk category	Other genitourinary procedures only in presence of infection
Most other congenital cardiac malformations (other than those listed above and below)	**Endocarditis prophylaxis not recommended**
Acquired valvar dysfunction (e.g., rheumatic heart disease)	Genitourinary tract
Hypertrophic cardiomyopathy	Vaginal hysterectomy[b]
Mitral valve prolapse with valvar regurgitation, thickened leaflets, or both	Urethral catheterization
Endocarditis prophylaxis not recommended	Uterine dilation and curettage
Negligible-risk category (risk no greater than that of the general population)	Therapeutic abortion
Isolated secundum atrial septal defect	Sterilization procedures
Surgical repair of atrial septal defect, ventricular septal defect, or patent ductus arteriosus (without residua beyond 6 months)	Insertion or removal of intrauterine device

[a] Prophylaxis is recommended for high-risk patients; option for medium-risk patients.

[b] Prophylaxis is option for high-risk patients.

From American College of Obstetricians and Gynecologists, 2006, and Dajani, 1997, with permissions.

Candidates for SBE prophylaxis are classified by their underlying cardiac disease and the degree of bacteremia anticipated from the planned surgical procedure. The American Heart Association identifies cardiac lesions as negligible, moderate, or high-risk for developing postprocedural infection (Dajani, 1997). For those at risk, antibiotics should be administered prior to the procedure. Recommended antibiotic prophylaxis guidelines endorsed by the American Heart Association and the American College of Obstetricians and Gynecologists are summarized in Table 39-9.

Table 39-9 Endocarditis Prophylaxis Regimens for Genitourinary and Gastroinestinal Procedures		
Situation	**Agents**	**Regimen**
High-risk patients	Ampicillin plus gentamicin	Adults: ampicillin 2.0 g IM or IV plus gentamicin 1.5 mg/kg (not to exceed 120 mg) within 30 min of starting procedure; 6 h later, ampicillin 1 g IM/IV or amoxicillin 1 g orally
High-risk patients allergic to ampicillin/amoxicillin	Vancomycin plus gentamicin	Adults: vancomycin 1.0 g IV over 1â€"2 h plus gentamicin 1.5 mg/kg IV/IM (not to exceed 120 mg); complete injection/infusion within 30 min of starting procedure
Moderate-risk patients	Amoxicillin or ampicillin	Adults: amoxicillin 2.0 g orally 1 h before procedure, or ampicillin 2.0 g IM/IV within 30 min of starting procedure
Moderate-risk patients allergic to ampicillin/amoxicillin	Vancomycin	Adults: vancomycin 1.0 g IV over 1â€"2 h; complete infusion within 30 min of starting procedure

IM = intramuscular; IV = intravenous.

From Dajani, 1997, with permission.

Gastrointestinal Bowel Preparation

Surgical dogma drives the use of mechanical bowel preparation as a means to prevent postoperative complications (Bucher, 2004). Studies conducted prior to the routine administration of antibiotic prophylaxis argued that bowel cleansing prior to colorectal surgery improved bowel handling, prevented anastomosis disruption with the passage of hard feces, and decreased fecal and bacterial loads. Thus, bowel cleansing was thought to reduce wound infection rates (Barker, 1971; Nichols, 1971).

Multiple recent studies, however, question the routine use of mechanical bowel preparations (Guenaga, 2003; Platell, 1998). Ram and co-workers (2005) prospectively randomized 329 patients undergoing elective large bowel resection to see whether routine mechanical bowel preparation reduced postoperative morbidity and mortality, including anastomotic breakdown and wound infections. They found no differences. Similar results have been found following gynecologic and urologic procedures (Muzii, 2006; Shafii, 2002). Moreover, a recent report contradicts the belief that mechanical bowel preparation decreases microbial contamination of the peritoneal cavity and subcutis after elective open-colon surgery (Fa-Si-Oen, 2005). It is not surprising to find that patients who do not have a mechanical bowel preparation are more satisfied and experience shorter times to their first postoperative bowel movement (Jung, 2007).

Although its routine use should be limited, mechanical bowel preparation is often preferred for many female pelvic reconstructive procedures involving the posterior vaginal wall and anal sphincter. In these cases, evacuation of rectal stool provides additional operating space and undistorted anatomy. Moreover, preoperative evacuation typically delays stooling and allows initial healing following sphincteroplasty. Other instances in which mechanical bowel preparation may be recommended include those in which the entire colon may be palpated during surgery for evaluation of tumor involvement. Table 39-10 provides a summary of various commercially available preparations used commonly for bowel preparation (Valantas, 2004).

Table 39-10 Colon Cleansing Preparation Methods

Diet and Cathartics	
Diet	Clear liquids for 3 days or a diet designed to leave a minimal colonic fecal residue for 1â€“3 days
Cathartics	Extract of senna fruit (X-Prep) 240 mL or magnesium citrate 240 mL
Additional cathartic	Bisacodyl 20 mg orally and suppositories
Enemas	Sodium phosphate or tap water
Kits	Liqui Prep, Nutra Prep, LoSo Prep System
Gut Lavage Methods	
Polyethylene glycolâ€“electrolyte lavage solution (PEG-ELS)	
Sodium sulfate and polyethylene glycol (PEG) GoLYTELY, CoLyte	
Sulfate-freeâ€“electrolyte lavage solution (SF-ELS)	
PEG without sulfate NuLYTELY	
Reduced volume with bisacodyl or magnesium citrate Half Lytely	
Phosphate Preps	
Oral sodium phosphate

Thromboembolism

PREVENTION

Venous thromboembolism (VTE) is a general category used to describe venous clot formation and includes the more specific entities of deep vein thrombosis (DVT) and pulmonary thromboembolism (PTE). Prophylaxis against VTE ranks in the top 10 patient safety practices recommended by the Agency for Healthcare Research and Quality (AHRQ) and the National Quality Forum (Michota, 2006). In the United States alone, it is estimated that the incidence of DVT approaches 450,000, with an additional 350,000 nonfatal PTE and 250,000 fatal PTE (Bick, 2002). National recommendations for prophylaxis against VTE follow a risk-based approach. The American College of Obstetricians and Gynecologists (2007) provides a summary of VTE risk factors pertinent during gynecologic surgery and successful prevention strategies of DVT/PTE (Table 39-11).

Table 39-11 Levels of Thromboembolism Risk in Surgical Patients Without Prophylaxis					
	DVT, %		PE, %		Successful Prevention Strategies
Level of Risk	**Calf**	**Proximal**	**Clinical**	**Fatal**	
Low risk	2	0.4	0.2	<0.01	No specific prophylaxis; early and "aggressive" mobilization
Minor surgery in patients <40 yr with no additional risk factors					
Moderate risk	10â€“20	2â€“4	1â€“2	0.1â€“0.4	LDUH (q12h), LMWH (≤ 3400 units daily), GCS, or IPC
Minor surgery in patients with additional risk factors Surgery in patients aged 40â€“60 yr with no additional risk factors					
High risk	20â€“40	4â€“8	2â€“4	0.4â€“1.0	LDUH (q8h), LMWH (≤ 3400 units daily), or IPC
Surgery in patients >40â€“60 yr with additional risk factors (prior VTE, cancer, molecular hypercoagulability)					
Highest risk	40â€“60	10â€“20	4â€“10	0.2â€“5	LMWH (>3400 units daily), fondaparinux, oral VKAs (INR 2â€“3), or IPC/GCS + LDUH/LMWH Consider continuing prophylaxis for 2â€“4 weeks after discharge
Surgery in patients with multiple risk factors (age >40 yr, cancer, prior VTE, or molecular hypercoagulability)					
Hip or knee arthroplasty,					
HFS Major trauma, SCI					

DVT = deep vein thrombosis; GCS = graduated compression stockings; HFS = hip fracture surgery; INR = international normalized ratio; IPC = intermittent pneumatic compression; LDUH = low-dose unfractionated heparin; LMWH = low-molecular-weight heparin; PE = pulmonary embolism; SCI = spinal cord injury; VKAs = vitamin K antagonists; VTE = venous thromboembolism.

From Geerts, 2004, and American College of Obstetricians and Gynecologists, 2007, with permission.

Hormone Discontinuation

Of risks, hormone use is one factor that can be modified prior elective surgery. Combined oral contraceptive pills (COCs) induce hypercoagulable changes that are reversed if COCs are stopped at least 6 weeks prior to surgery (Robinson, 1991; Vessey, 1986). To balance the risk of unintended pregnancy in women halting COCs, a suitable alternative is recommended with clear instructions on use.

Postmenopausal hormone replacement therapy (HRT) appears also to increase the incidence of postoperative VTE. Grady and colleagues (2000) estimate a fivefold increase in the risk of developing a venous thrombotic event during the first 90 days after inpatient surgery. Thus, women should be counseled appropriately on this additional postoperative risk, but the value and duration of HRT cessation to negate this increased risk are unclear.

Prophylaxis Options

Various modalities for prophylaxis exist. Early ambulation, though encouraged after surgery, is not regarded as a primary strategy

for DVT prophylaxis (Michota, 2006). Graded compression stockings (TED hose), when used in conjunction with other methods of prophylaxis, offer additional benefit (Amaragiri, 2000). Intermittent pneumatic compression (IPC) works primarily by improving venous flow. It appears to be effective in moderate- and high-risk patients if initiated prior to the induction of anesthesia and continued until patients are fully ambulatory (Clarke-Pearson, 1993; Geerts, 2004). Pharmacologic methods of VTE prophylaxis include low-dose unfractionated heparin, low-molecular-weight heparin, and new classes of medications such as factor Xa inhibitors.

DIAGNOSIS AND TREATMENT OF THROMBOEMBOLISM

If VTE is suspected, evaluation begins with clinical examination and estimation of the woman's likelihood for disease. Wells and colleagues (1995) published one of the most widely used clinical prediction algorithms (Fig. 39-4 and Table 39-12). When indicated, duplex sonography is highly sensitive for detecting proximal DVT, with a false-negative rate of 0 to 6 percent (Gottlieb, 1999). For PTE, clinicians continue to use ventilation-perfusion (VQ) scanning and helical computed-tomographic (CT) scanning as alternatives to the invasive "gold standards"â€”pulmonary angiography or contrast venography.

Table 39-12 Pretest Probability for Deep Vein Thrombosis

Clinical Probability
High ≥3 major points and no alterative diagnosis ≥2 major points and ≥2 minor points + no alternative diagnosis
Low 1 major point + ≥2 minor points + has an alterative diagnosis 1 major point + ≥1 minor point + no alterative diagnosis 0 major points + ≥3 minor points + has an alterative diagnosis 0 major points + ≥2 minor points + no alterative diagnosis
Moderate All other combinations

Algorithm for evaluation of suspected deep vein thrombosis (DVT). PTP = pretest probability. *(From Wells, 1995, with permission.)*

Acute management of VTE involves anticoagulation with intravenous unfractionated heparin or subcutaneous low-molecular-weight heparin. After achieving adequate anticoagulation, oral vitamin K antagonists such as warfarin are initiated. Therapy duration is dictated by clinical circumstance and typically is administered for: (1) 3 to 6 months following a first idiopathic DVT, (2) 6 months for PTEs, and (3) indefinitely for those with a thrombophilic condition or a second VTE.

Postoperative Nausea and Vomiting

This is one of the most common complaints following surgery, and its incidence ranges from 30 to 70 percent in high-risk patients (Moller, 2002). Those at risk for postoperative nausea and vomiting (PONV) include females, nonsmokers, those with a history of motion sickness or PONV, those with extended surgeries, and those undergoing laparoscopic or other gynecologic surgery (Apfelbaum, 2003).

A multimodal approach to prevention is recommended (Apfel, 2004). Currently, combinations of 4 to 8 mg dexamethasone prior to anesthesia induction are followed by less than 1 mg droperidol and 4 mg ondansetron toward the end of surgery. This pretreatment significantly reduces symptoms by 25 percent. However, if symptoms develop within 6 hours of surgery, antiemetics from a different pharmacologic class than previously administered should be considered (Habib, 2004). Persistent nausea may benefit from combining agents from different classes (Table 39-13).

Table 39-13 Commonly Used Medications for Nausea and Vomiting

Class/Medication	Usual Dosage	Route(s)	Adverse Effects
Anticholinergic			
Scopolamine (Transderm Scop)	1 patch every 3 d	Transdermal	Dry mouth, drowsiness, impaired eye accommodation
Antihistamines			
Diphenhydramine (Benadryl)	25â€“50 mg q4â€“6h	IM, IV, PO	Sedation, dry mouth, constipation, blurred vision, urinary retention
Hydroxyzine (Atarax, Vistaril)	25â€“100 mg q6h	IM, PO	
Meclizine (Antivert)	25â€“50 mg q6h	PO	
Promethazine (Phenergan)	12.5â€“25 mg q4â€“6h	IM, IV, PO, PR	
Benzamides			
Metoclopramide (Reglan)	5â€“15 mg q6h	IM, IV, PO	Sedation or agitation, diarrhea, extrapyramidal effects, hypotension
Trimethobenzamide (Tigan)	250 mg q6â€“8h	IM, PO, PR	
Benzodiazepines			
Lorazepam (Ativan)[a]	0.5â€“2.5 mg q8â€“12h	IM, IV, PO	Sedation, amnesia, respiratory depression, blurred vision, hallucinations
Corticosteroids			
Dexamethasone (Decadron)[a]	4 mg q6h	IM, IV, PO	GI upset, anxiety, insomnia, hyperglycemia
Phenothiazines			
Prochlorperazine (Compazine)	5â€“10 (25 PR) mg q6h	IM, IV, PO, PR	Sedation, extrapyramidal effects, cholestatic jaundice, hyperprolactinemia
5-HT3 Serotonin Antagonists			
Ondansetron (Zofran)	8 mg q8h	IV, PO	Headache, fever, arrhythmias, ataxia, somnolence or nervousness, elevated hepatic transaminases
Granisetron (Kytril)	2 mg per 24 h	IV, PO	
Dolasetron (Anzemet)	100 mg per 24 h	IV, PO	

GI = gastrointesintal; HT = hydroxytryptamine; IM = intramuscular; IV = intravenous; PO = orally; PR = per rectum.

POSTOPERATIVE CONSIDERATIONS

Thorough preoperative planning, awareness of common postoperative complications, and vigilance to details will ensure successful convalescence for most patients.

Postoperative Orders

Postoperative orders provide instruction regarding support of each organ system while normal function is gradually reestablished. Although orders are customized for each woman, goals are common among all surgical patientsâ€”resuscitation, pain control, and resumption of daily activities. Table 39-14 offers a template for both inpatient and outpatient postoperative orders.

Table 39-14 Typical Postoperative Orders (Inpatient and Outpatient)

Postoperative Orders (Inpatient)	Postoperative Orders (Outpatient)
Admit to: recovery room/assigned hospital floor/attending physician's name	Admit to: recovery room; transfer to DSU when cleared by anesthesia
Diagnosis: s/p what surgical procedure	Diagnosis: s/p what surgical procedure
Condition: stable	Condition: stable
Vital signs: q1h $\times$ 4, q2h $\times$ 2, then q4h	VS per routine
Activity: bed rest	Allergies: NKDA
Allergies: NKDA	Bed rest until A&A, then activity ad lib
Notify MD for: T > 101Â°F; BP > 160/110, <90/60; P > 130; RR > 30, <10; UOP < 120 mL/4 h; acute changes	NPO until A&A, then clear liquids
Diet: NPO except ice chips	IV fluids: LR at 125 mL/h until tolerating PO, then D/C IV
IV fluids: LR at 125/h	Notify MD for: T > 101Â°F; BP > 160/110, <90/60; P > 130; RR > 30, <10; acute changes
Special: Strict I/Os Turn, cough, deep breath q1h while awake IS to BS, q1h while awake Foley to gravity SCD hose to pump	D/C patient home when A&A, cleared by anesthesia, taking PO, ambulating, & able to void
Medications: 1. PCA orders: mix 30 mg MSO_4 in 30 mL NS; load 4â€“6 mg, then IV q6min on demand; lockout 20 mg in 4 hours	F/U at ____________ clinic in _____ weeks

2. Phenergan 25 mg IV q6h prn N/V 3. Â±Toradol 30 mg IM q6h x 24 h (only if Cr is okay)	
Labs: H&H in am (or that afternoon if necessary)	Write any necessary prescriptions

A&A = awake and alert; BS = bedside; Cr = creatinine; D/C = discontinue; DSU = day surgery unit; F/U = follow-up; H&H = hemoglobin and hematocrit; I/Os = input and output; IM = intramuscular; IS = incentive spirometry; IV = intravenous; LR = lactated Ringer's; MSO_4 = morphine sulfate; NKDA = no known drug allergies; NPO = nil per os; NS = normal saline; N/V = nausea and vomiting; PCA = patient-controlled analgesia; PO = per os; RR = respiratory rate; SCD = sequential compression device; s/p = status post; UOP = urine output; VS = vital signs.

Pain Management

Postoperative pain management remains undervalued, and many patients continue to experience pain after surgery. A recent survey by Apfelbaum and colleagues (2003) revealed that more than 85 percent of respondents following surgery have moderate to severe pain. Poor pain control leads to decreased satisfaction with care, prolonged recovery time, increased use of health care resources, and increased health care costs (Joshi, 2005).

NONOPIOID TREATMENT OPTIONS

The two major classes of nonopioid therapies are acetaminophen and nonsteroidal anti-inflammatory drugs (NSAIDs). In general, these drugs are well tolerated and carry a low risk of serious side effects. However, acetaminophen can be toxic to the liver in high doses. Thus, dosages greater than 4,000 mg/d should be avoided, especially if providing combination therapy with oral opioids and nonopioid drugs. If given preoperatively, NSAIDs reduce postoperative pain, lower the amount of required opiates, and decrease the incidence of PONV by as much as 30 percent (Adachi, 2007; Akarsu, 2004; Chan, 1996; Mixter, 1998).

OPIOID TREATMENT OPTIONS

Despite the common side effects that all opiates shareâ€"respiratory depression and nausea and vomitingâ€"opiate therapy is the primary choice for managing moderate to severe pain. The three most commonly prescribed opiates after gynecologic surgeries are morphine, fentanyl, and hydromorphone. Meperidine, although administered commonly in many obstetric units, is avoided in part because of neurologic side effects associated with its active metabolite, normeperidine. Normeperidine is a cerebral irritant that can cause effects ranging from irritability to seizure.

Morphine

Morphine, the most commonly prescribed opiate following gynecologic surgery, is a potent μ-opiate receptor agonist. Action at this receptor accounts for the analgesia, euphoria, respiratory depression, and decreased gastrointestinal motility seen with morphine. Onset of action is rapid, with the peak effects being seen within 20 minutes of intravenous administration. Its action typically lasts for 3 to 4 hours. Its active metabolite, morphine-6-glucuronide, is excreted renally and thus is well tolerated in low doses in those with liver disease. Pruritus is common following administration, although its genesis is poorly understood. Some investigators theorize that central opiate receptors are stimulated, whereas others speculate a histamine release, as evidenced by urticaria, wheals, and flushing (Bergasa, 1991).

Fentanyl

This potent synthetic opiate is more lipophilic than morphine and displays a shorter duration of action and half life. Peak analgesia occurs within minutes of intravenous administration and lasts for 30 to 60 minutes. Many conscious sedation protocols used during office gynecologic procedures combine fentanyl with a sedative such as midazolam.

Hydromorphone

Hydromorphone, another semisynthetic analogue of morphine, is less lipophilic than fentanyl. It is available for delivery by multiple routes, including oral, intramuscular, intravenous, rectal, and subcutaneous. Hydromorphone achieves its peak analgesia 15 minutes after intravenous administration, and its effect last 3 to 4 hours. Although commonly used during epidural analgesia,

hydromorphone is a suitable patient-controlled analgesia (PCA) alternative in patients with a morphine allergy. Table 39-15 provides a summary of the various pain medications, with equivalent dosages listed.

Table 39-15 Opiod Equivalency Chart/Dosing Data for Opioids

	Approximate Opioid Equianalgesic Dose			Usual Starting Dose			
Drug	**Parenteral (mg)**	**Oral (mg)**	**Duration (h)**	**Adults > 50 kg Body Wt.**		**Children and Adults < 50 kg**	
				Parenteral	**Oral**	**Parenteral**	**Oral**
Morphine IR (Roxanol)	10	30	3â€“4	10 mg	30 mg	0.1 mg/kg	0.3 mg/kg
Morphine SR (Oramorph) (MS contin)	â€”	30	8â€“12	â€”	30 mg	â€”	0.3 mg/kg
Meperdine (Demerol)	75	300	2â€“3	100 mg	NR	0.75 mg/kg	NR

SYSTEM-BASED COMPLICATIONS

Postoperative Urinary Retention

Inability to void with a full bladder is a common problem after gynecologic surgery, and incidences range from 7 to 80 percent depending on the definition used and the surgical procedure (Stanton, 1979; Tammela, 1986). Overdistention can lead to prolonged difficulty with micturition and even permanent detrusor damage (Mayo, 1973). In addition to patient discomfort, recatheterization to treat retention increases the risk of urinary tract infection and may extend hospitalization.

Keita and colleagues (2005) prospectively evaluated risk factors potentially predictive of early postoperative urinary retention. Three major factors were independently associated with an increased riskâ€”age older than 50 years, intraoperative fluid administration greater than 750 mL, and bladder urine volume greater than 270 mL measured on entry to the recovery room. Among gynecologic procedures, the risk is higher after laparotomy compared with laparoscopy (Bodker, 2003).

Despite identifiable risks, all women should be advised of the need for immediate evaluation in the event of absent or difficult voiding. Clinical markers include pain, tachycardia, urge to void without success, and bladder enlargement by palpation or

percussion. These clinical markers have been found to be equivalent to evaluation of urine volume using bedside bladder sonography (Bodker, 2003).

Once retension is identified, catheterization and bladder drainage should follow. Lau and Lam (2004) sought to determine the best catheterization strategy for managing postoperative urinary retention. Compared with overnight bladder decompression with an indwelling catheter, episodic in-and-out catheterization is equally effective. Moreover, infectious morbidity between the two does not differ significantly.

VOIDING TRIALS

Normal urination requires appropriate bladder contractility in the absence of significant urethral resistance (Abrams, 1999). Objective criteria that define "normal function" postoperatively vary and may be assessed using either active or passive voiding trials.

Active Voiding Trial

During this test, the bladder is actively filled with a set volume, and following patient voiding, residual bladder urine volumes are calculated. Initially, the bladder is emptied completely by catheterization. It may be helpful during catheterization for a woman to stand upright to clear the most dependent portions of her bladder. Sterile water infused under gravity then is instilled into the bladder through the same catheter until approximately 300 mL is used or until a subjective maximum capacity is reached. The patient then is given up to 30 minutes to void spontaneously into a urine collection device. The difference between volume infused and volume retrieved is recorded as the *postvoid residual.*

The only published study evaluating the effectiveness of this strategy was reported by Kleeman and colleagues (2002). They evaluated women following surgery for incontinence and prolapse. In their study, a postvoid residual of less than 50 percent carried a recatheterization rate of 8 percent. If patients could void more than 70 percent of the instilled volume spontaneously, there were no failures.

Passive Voiding Trial

As an alternative to active saline instillation, voiding and residuals may be assessed following passive, physiologic filling of the bladder. Initially, the Foley catheter is removed, and a woman is encouraged to drink increased amounts of liquid. She is encouraged to void spontaneously at her first urge to urinate or after 4 hours, whichever is first. Urine volume in a collection device is measured. An in-and-out catheterization or bladder sonogram is then performed to measure the postvoid residual.

An easy rule to remember for evaluating either active or passive voiding trials is the *75/75 rule* â€”spontaneously voiding greater than 75 mL *and* voiding greater than 75 percent of the total volume. This constitutes a successful voiding trial and obviates the need for Foley catheter reinsertion. Alternatively, on the Female Pelvic Medicine and Reconstructive Surgery Service at our institution, a postvoid residual of less than 100 mL constitutes a success.

Pulmonary Complications

Broad definitions hinder our ability to assess the incidence of postoperative pulmonary complications accurately, but reported estimates range from 9 to 69 percent (Calligaro, 1993; Hall, 1991; Qaseem, 2006). Common pulmonary complications encountered by gynecologists are atelectasis and pneumonia. Five significant risk factors for pulmonary complications following abdominal surgery include age older than 60 years, body mass index (BMI) greater than 27, a history of cancer, smoking within the past 8 weeks, and a surgical incision involving the upper abdomen (Brooks-Brunn, 1997).

ATELECTASIS

This condition is characterized by decreased breath sounds or dullness to percussion over affected lung fields. In addition, linear densities in the lower lung fields typify chest radiographic features (Hall, 1991). Classically, atelectasis is associated with low-grade fever. However, Engoren and colleagues (1995) evaluated 100 consecutive adult postoperative patients with radiographically diagnosed atelectasis and found no association between atelectasis and postoperative fever. Despite its common occurrence after abdominal operations, this condition is usually temporary, self-limited, and rarely slows patient recovery or hospital discharge (Platell, 1997). Severe cases of atelectasis can be prevented in many instances using lung expansion therapies described earlier

(Lung Expansion Modalities).

HOSPITAL-ACQUIRED PNEUMONIA

This is the second most common nosocomial infection in the United States and carries high associated morbidity and mortality (Tablan, 2004). Its incidence in surgical patients varies and ranges from 1 to 19 percent depending on surgical procedure and hospital surveyed (Kozlow, 2003). Of these infections, bacterial pathogens most typically responsible include aerobic gram-negative bacilli, such as *Pseudomonas aeruginosa* , *Escherichia coli* , *Klebsiella pneumoniae* , and *Acinetobacter* species.

Clinically, pneumonia is diagnosed if chest radiography reveals a new or progressive radiographic infiltrate and if two of three clinical features (i.e., leukocytosis, fever greater than 38Â°C, or purulent secretions) are present. An algorithm supported by the American Thoracic Society is shown in Figure 39-5. As discussed earlier, prevention can be accomplished by using oral endotracheal and orogastric tubes in place of nasal tubes; elevating the head of the bed 30 to 45 degrees, particularly during feeding; and aspiration of subglottic secretions in those unable to clear them (American Thoracic Society, 2005).

Gastrointestinal Considerations

RESUMPTION OF BOWEL FUNCTION

Normal gastrointestinal function requires synchronized motility throughout the system, mucosal transport of nutrients, and evacuatory reflexes (Nunley, 2004). However, following intra-abdominal surgery, dysfunction of enteric neural activity typically disrupts normal propulsion. Activity first returns in the stomach and is noted typically within 24 hours. The small intestine also exhibits contractile activity within 24 hours of surgery, but normal function may be delayed for 3 to 4 days (Condon, 1986; Dauchel, 1976). Rhythmic colonic motility resumes last, at approximately 4 days following intra-abdominal surgery (Huge, 2000). Passage of flatus characteristically marks this return of function, and stool passage typically follows in 1 to 2 days.

RESUMPTION OF DIET

Postoperative feeding has been found to be most effective when started immediately postoperatively. Early feeding has been shown to improve wound healing, stimulate gut motility, decrease intestinal stasis, increase splanchnic blood flow, and stimulate reflexes that elicit secretion of gastrointestinal hormones that can shorten postoperative ileus (Anderson, 2003; Braga, 2002; Correia, 2004; Lewis, 2001). The decision to initiation "early feeding" with liquids or with solid food has been studied prospectively (Jeffery, 1996). In patients who were given solid food as the first postoperative meal, the number of calories and protein consumed on the first postoperative day were higher. In addition, the number of patients requiring diet changes to NPO was not statistically different (7.5 percent in the regular diet group and 8.1 percent in the clear diet group). The improved tolerance and better palatability of solids make this a reasonable option.

ILEUS

Postoperative ileus (POI) is a transient impairment of gastrointestinal activity that leads to abdominal distention, hypoactive bowel sounds, nausea and/or vomiting related to gastrointestinal gas and fluid accumulation, and delayed passage of flatus and/or stool (Livingston, 1990).

The genesis of postoperative ileus is multifactorial. First, bowel manipulation during surgery leads to production of factors that contribute to POI: (1) neurogenic factors related to sympathetic overactivity, (2) hormonal factors through the release of hypothalamic corticotropin-releasing factor (CRF), which plays a key role in the stress response, and (3) inflammatory factors (Tache, 2001). Additionally, perioperative opioid use also has a significant role in the etiology of POI. Thus, in selecting these agents, clinicians should balance the beneficial analgesia produced by central opioid receptor binding against the gastrointestinal dysfunction that results from peripheral receptor-binding effects (Holzer, 2004).

No single treatment defines the management of POI. Electrolyte repletion and intravenous fluids to reestablish a euvolemic state constitute traditional therapy. In contrast, routine NGT decompression to promote bowel rest has been challenged by multiple prospective, randomized trials. A recent meta-analysis including nearly 4,200 patients found routine NGT decompression unsuccessful and inferior to its selective use in symptomatic patients. Specifically, patients without NGTs had significantly earlier return of normal bowel function and decreased risks of wound infection and ventral hernia (Nelson, 2005). Additionally, tube-related discomfort, nausea, and hospital stays were reduced. For these reasons, postoperative NGTs are recommended only for symptomatic relief of abdominal bloating and recurrent vomiting (Nunley, 2004).

Gum chewing as a preventative modality for POI has been the focus of several recent studies. Most authors conclude that gum chewing offers no therapeutic value given that there were no significant differences in length of hospitalization or time to first gas or stool passage (Matros, 2006).

SMALL BOWEL OBSTRUCTION

Obstruction of the small intestines may be partial or complete and can result from adhesions following intra-abdominal surgery, infection, or malignancy. Of these, surgical adhesions are the most common cause (Krebs, 1987; Monk, 1994). Small bowel obstruction (SBO) is estimated to develop following 1 to 2 percent of total abdominal hysterectomies, and nearly 75 percent are complete obstructions (Al Sunaidi, 2006). The mean interval between a primary intra-abdominal procedure and SBO is approximately 5 years (Al Took, 1999).

Although the initial management of a SBO is similar to that for postoperative ileus, distinguishing between the two entities is important to prevent serious SBO sequelae. During SBO, the bowel lumen dilates proximal to the obstruction, whereas decompression may develop distally. Bacterial overgrowth in the proximal small bowel may lead to bacterial fermentation and worsening dilation. The bowel wall continues to become edematous and dysfunctional (Wright, 1971). Progressive increases in bowel pressure can compromise perfusion to the intestinal segment and lead to rupture (Megibow, 1991).

Clinical signs that may help to distinguish SBO from POI include tachycardia, oliguria, and fever. Physical examination may reveal abdominal distention, high-pitched bowel sounds, and an empty rectal vault on digital examination. Finally, leukocytosis with a left shift should alert the clinician to possible coexisting bowel ischemia.

For diagnosis, CT scanning is the primary imaging tool to identify SBO. Water-soluble contrast material can help to identify the

cause and severity of an obstruction. Gastrografin, the most commonly used water-soluble dye, is a mixture of diatrizoate meglumine and diatrizoate sodium and aids resolution of small bowel edema because of its high osmotic pressure. Gastrografin (Bracco Diagnostics, Anjou, Quebec) is also theorized to enhance smooth muscle contractility (Assalia, 1994). Although the use of oral Gastrografin does appear to reduce hospital length of stay, it has no therapeutic benefit in adhesion-related SBO (Abbas, 2005).

Nutrition

The primary goals of postoperative nutrition are to improve immune function and promote wound healing while minimizing metabolic disturbances. Despite the additional stress in the immediate postoperative period, underfeeding is accepted for a brief period of time (Seidner, 2006). Table 39-16 offers a summary of the basic metabolic needs in the immediate postoperative period. However, extended protein-calorie restriction in a surgical patient can lead to impaired wound healing, diminished cardiac and pulmonary function, bacterial overgrowth within the gastrointestinal tract, and other complications that increase hospital stays and patient morbidity (Elwyn, 1975; Kinney, 1986; Seidner, 2006). If substantial oral caloric intake is delayed for 7 to 10 days, nutritional support is warranted.

Table 39-16 Postoperative Nutritional Requirements

Nutritional Requirements	**Recommendations**
Basal energy expenditure (BEE) in women	65.5 + 1.9 (height [cm]) + 9.6 (weight [kg]) â€“ 4.7 (age [yr])
Total calories	100% to 120% BEE
Glucose	50â€“70% total caloric intake
	Maintain blood glucose level < 200 mg/dL
Protein	1.5 g/kg/d of current weight (BMI < 25)
	2.0 g/kg/d of ideal weight (BMI > 25)

BMI = body mass index.

Compiled from Nehra, 2002.

ENTERAL VERSUS PARENTERAL NUTRITION

In the absence of contraindications, enteral nutrition is preferred to a parenteral route, especially when infectious complications are compared (Kudsk, 1992; Moore, 1992). Other advantages of enteral nutrition include fewer metabolic disturbances and lower cost (Nehra, 2002).

Hypovolemic Shock

DIAGNOSIS OF HYPOVOLEMIC SHOCK

Circulatory dysfunction causes decreased tissue oxygenation and results in multiorgan failure if not recognized and treated promptly. In gynecology, the most common cause of shock is hemorrhage-related hypovolemia, although cardiogenic, septic, and neurogenic shock should be considered during patient evaluation. Assessment of oxygen perfusion and hemodynamic status is critical in the early postoperative period. Unfortunately, markers such as blood pressure and resting heart rate may be unaffected through early compensation. For example, after an acute blood loss of greater than 25 to 30 percent of total blood volume, hypotension typically lags other markers of multiorgan dysfunction, including oliguria and altered mental status.

In addition to a heightened clinical suspicion of hypovolemia, serum markers may help to provide objective evidence of decreased perfusion and oxygenation. Serum lactate levels have been shown to be more sensitive than blood pressure and cardiac output in predicting severe hemorrhage (Broder, 1964; Dunham, 1991). In addition, serum lactate levels can be used to guide the

effectiveness of resuscitation. Blood gas analysis also can provide a rapid estimate of the serum base deficit. Hemorrhage severity can be predicted accurately using the following stratification: â€“2 to â€“5 (mild hemorrhage), â€“6 to â€“14 (moderate hemorrhage), and â€“15 or less (severe hemorrhage). If patients continue to have dropping base deficits despite aggressive resuscitation, ongoing hemorrhage should be assumed (Davis, 1988). Of note, immediate hematocrit levels do not predict the severity of acute blood loss as accurately as serial trends.

TREATMENT OF HYPOVOLEMIC SHOCK

Treatment of hypovolemic shock centers on control of ongoing hemorrhage and restoration of intravascular volume. One easy mnemonic used to describe treatment is *ORDER* , which represents *o* xygenate, *r* estore, *d* rug therapy, *e* valuate, and *r* emedy (American College of Obstetricians and Gynecologists, 1997). Initially, supplemental oxygen is provided to avoid tissue desaturation (Wilson, 2003). Simultaneously, a rapid infusion of isotonic crystalloid solutions through two large-bore intravenous lines can quickly replace volume. In the face of refractory hypotension, supplemental colloids and red blood cell transfusion may be necessary (see Chap. 40, Fluid Resuscitation and Blood Transfusion). In the presence of hypovolemia, vasopressors generally are not recommended except to temporarily assist with an unstable condition while fluid resuscitation is administered. During treatment, resuscitation efforts are monitored continuously through central venous pressures, urine output, and the patient's general status. Finally, if ongoing bleeding is suspected, the benefits of operative intervention may outweigh the risks of continued conservative therapy. Intraoperatively, isolation and control of hemorrhage should be approached systematically (see Chap. 40, Steps of Hemorrhage Management).

After the patient is stabilized, close surveillance for electrolyte abnormalities, coagulation imbalance, and ischemic organ injury is essential.

Postoperative Fever Evaluation

One of the most common problems encountered postoperatively is fever. Although fever may reflect an infectious process, most are self-limited (Garibaldi, 1985). However, for those with persistent symptoms, a systematic approach to patient evaluation will help to differentiate inflammatory from infectious etiologies.

PATHOPHYSIOLOGY OF THE FEBRILE RESPONSE

Fever is a response to inflammatory mediators, termed *pyrogens* , that originate either endogenously or exogenously. Circulating pyrogens lead to the production of prostaglandins (primarily PGE_2), which elevate the thermoregulatory set point. The inflammatory cascade produces a number of cytokines (interleukin-1, interleukin-6, tumor necrosis factor α) found in the circulation after a variety of eventsâ€”surgery, cancer, trauma, and infection (Wortel, 1993). Thus, a differential diagnosis of a postoperative fever should include noninfectious and infectious causes.

ETIOLOGY

Postoperative fevers that develop more than 2 days following surgery are more likely to be infectious. The most common causes may be broadly categorized and are reflected in the mnemonic, the *five W's.* These represent wind, water, walking, wound, and wonder drug. First, pneumonia should be considered, and women at greatest risk are those who have been mechanically ventilated for a prolonged period, have an NGT in place, or have pre-existing COPD. Additionally, catheterization places women at risk for developing a urinary tract infection. Logically, duration of catheterization correlates positively with the risk for this infection. Venous thromboembolic disease may present with low-grade fever, and patients with VTEs commonly present with other disease-specific symptoms. For example, women with DVT often complain of unilateral lower extremity edema and erythema. Those with PTE may note dyspnea, cough with blood-tinged sputum, chest pain, tachycardia, and symptoms of hypotension (Stein, 2000). Fever related to surgical site infections usually develops 5 to 7 days after surgery. These infections may involve the pelvis or abdominal wall layers, and their management is discussed later in this chapter and in Chapter 3, Pain. Finally, medications commonly used postoperativelyâ€”such as heparin, beta-lactam antibiotics, and sulfonamide antibioticsâ€”may cause a rash, eosinophilia, or drug fever.

CLINICAL EVALUATION

Evaluations that rotely include CBC, urinalysis, blood cultures, and chest radiographs have been evaluated in multiple studies and

are inefficient and ineffective (Badillo, 2002; de la Torre, 2003; Schey, 2005). Thus, initial assessment of a woman with postoperative fever should be individualized and begin with a focused history and physical examination. The simple diagnostic algorithm presented in Figure 39-6 can be used as one high-yield, cost-effective strategy for the management of a woman with postoperative fever.

Wound Dehiscence

Despite the clinical advances made in the arenas of anesthesia, preoperative antibiotics, suture technology, and postoperative care, the incidence of wound disruptions remains largely unchanged (Cliby, 2002). Dehiscence prolongs hospital stay and requires labor-intensive care. Thus, a surgeon should have knowledge of modifiable risk factors and treatment options for these complications.

CLASSIFICATION AND INCIDENCE

The level to which a wound may open varies and may involve the subcutaneous and skin layers. More seriously, separation also may include abdominal wall fascia. Superficial separations often follow a wound infection originating from a hematoma or seroma and have a reported incidence of between 3 and 15 percent (Owen, 1994; Taylor, 1998). Fascial dehiscences, on the other hand, occur less frequently and are fatal in nearly 25 percent of cases (Carlson, 1997). Fascial necrosis from sutures held under too much tension leads to failure of sutures to remain anchored in the fascia (Bartlett, 1985). These layers then may separate with only minimal increases in intra-abdominal pressure.

Wound classification greatly predicts the subsequent risk of developing a postoperative wound infection (Cliby, 2002). For those with clean wounds, the risk of infection is less than 5 percent; those with clean contaminated wounds, 2 to 10 percent; those with contaminated wounds, 15 to 20 percent; and those with dirty wounds, more than 30 percent. Descriptive criteria for these wound categories are found in Table 3-30.

PREVENTION

In addition to wound type, other important risk factors for developing a wound dehiscence include general patient health, proper surgical technique, and appropriate timing of preoperative antibiotics.

General Patient Health

Riou and colleagues (1992) found that age greater than 65 years, pulmonary disease, malnutrition, obesity, malignancy, and hypertension contribute to a patient's risk of developing subsequent wound disruption. Diabetes mellitus and smoking are two other contributors to surgical site infections that lend themselves to preoperative optimization (Cheadle, 2006). Although many of these are not modifiable, the presence of these risks should prompt increased surveillance postoperatively.

Proper Surgical Technique

In the operating room, a surgeon has multiple opportunities to modify risks associated with wound disruption. Proper surgical technique maintains hemostasis, handles tissues gently, removes devitalized tissue, closes dead spaces, encourages use of monofilament suture, includes indicated placement of closed suction drains, and sustains normothermia (Mangram, 1999). For example, Kurz and co-workers (1996) demonstrated that maintaining normothermia in patients undergoing abdominal surgery significantly reduced postoperative wound infection rates from 19 to 6 percent.

Use of electrosurgery instead of scalpel for abdominal entry is common and offers speed, hemostasis, comparable wound healing, and decreased requirements for postoperative analgesia (see Chap. 40, Electrosurgery) (Chrysos, 2005). The cutting properties of electrosurgery cause cells to explode by conversion of cell water to steam. This method of heat dissipation leads to minimal lateral thermal tissue damage. Coagulation mode, on the other hand, achieves hemostasis through formation of a superficial eschar and desiccation (the fibrous binding between dehydrated, denatured cells of vessel endothelium). Therefore, tissue dissection should be performed using a cutting mode, whereas hemostasis is best achieved with directed coagulation. In addition, less tissue damage and fewer tracts for bacterial overgrowth result from minimizing the number of surgical strokes during incision.

Dead space closure using a subcutaneous suture in Camper fascia at the time of cesarean delivery has been shown to reduce superficial wound disruptions significantly in those with at least 2-cm subcutaneous depth (Naumann, 1995). Well-designed prospective studies in gynecologic populations are lacking. Skin closure using subcuticular suturing has lower wound separation rates than staples (Johnson, 2006).

DIAGNOSIS

Superficial wound separations usually present 3 to 5 days after surgery, with wound erythema and new-onset drainage. Once identified, an isolated wound cellulitis often can be treated with systemic antibiotics. However, a delay in evacuating infected inflammatory exudates from the subcutaneous layer dead space can weaken fascia and increase the risk of fascial dehiscence.

Fascial dehiscences generally present within the first 10 days postoperatively. Superficial disruption of the subcutaneous layer and extensive leakage of peritoneal fluid/purulent drainage are indicative. Given the high mortality risk associated with fascial dehiscence and bowel evisceration, examination under anesthesia to estimate the extent of separation is warranted.

TREATMENT OF SUPERFICIAL WOUND DEHISCENCE

The focus of wound management should be to expedite healing while minimizing complications and costs.

Wet-to-Dry Dressing Changes

The initial focus of wound management is evacuation of all hematomas and/or seromas and treatment of underlying infection. Modern wound care has revised some of the classic axioms behind healing through secondary intention.

Irrigation used for wound dressings should remove surface bacteria without disrupting normal healing components. Povidone-

iodine, iodophor gauze, dilute hydrogen peroxide, and Daiken solution are cytotoxic to white blood cells and should not be used in wound care (Bennett, 2001; O'Toole, 1996).

Ideally, wound dressings are removed daily and replaced with properly hydrated materials. In very necrotic wounds, allowing gauze to dry and pulling tissue adherent to the gauze with each change is acceptable. More frequent changes should be avoided because they lead to aggressive dÃ©bridement of vital tissues and slow wound healing. Table 39-17 lists products used in modern wound care.

Table 39-17 Wound Care Products

Product	Description
Antifungal cream	Topical cream used as treatment for superficial fungal infections of the periwound skin; contains 2% miconazole nitrate.
Calcium alginate	Calcium alginate is a solid that exchanges calcium ions for sodium ions when it contacts any substance containing sodium such as wound fluid. The resulting sodium alginate is a gel that is nonadhesive, nonocclusive, and conformable to wound bed. Indicated for moderately or highly draining wounds.
Enzymatic dÃ©brider	Topical solution that breaks down necrotic tissue by directly digesting the components of slough or by dissolving the collagen that holds necrotic tissue to the underlying wound bed.
Film	Thin, transparent polyurethane sheets coated on one side with acrylic, hypoallergenic adhesive. The adhesive will not stick to moist surfaces, and the film is impermeable to fluids and bacteria, but semipermeable to oxygen and water vapor. Indicated in superficial wounds with little or no exudate.
Foam	Polyurethane sheets containing open cells capable of holding fluids and pulling them away from the wound bed. Foams provide absorbency while keeping the wound moist. Indicated in moderately or highly draining wounds.
Gauze	Woven or nonwoven cotton or synthetic blends.
Hydrogel	Formulated in sheets or gels. Glycerin-, saline-, or water-based to hydrate the wound. Indicated in dry or minimally draining wounds.
Silver nitrate	Used to treat overgrown granulation tissue. Apply stick to hypergranulation tissue.

Negative-Pressure Wound Therapy

This therapy generates subatmospheric pressure by a wound vacuum device that is applied either continuously or intermittently to an open subcutaneous wound. The negative pressure generated by such devices offers three benefits to wound care: (1) evacuates wound drainage to reduce bacterial colonization, (2) promotes release of cytokines that are helpful in wound healing, and (3) increases blood flow and oxygenation to tissues to uniformly reduce wound size and improve angioneogenesis (Fabian, 2000; Morykwas, 1997).

Delayed Primary Closure

Approximately 4 days after wound disruption and resolution of subcutaneous infection, a superficial vertical mattress suture closure may be used to reapproximate subcutaneous and skin tissue edges (Wechter, 2005). Overall, this strategy reduces healing time by 5 to 8 weeks and significantly decreases the number of postoperative visits. Bedside closure is typically well tolerated using local anesthesia and 2-0 polypropylene suture. Alternatively, wounds may be allowed to close by secondary intention.

TREATMENT OF FASCIAL DEHISCENCE

Early recognition of abdominal wall separation is critical in reducing serious morbidity and mortality associated with fascial

dehiscence. This is regarded as a surgical emergency, and a gynecologist must first determine if a fascial dehiscence is associated with evisceration of abdominal contents. If discharge of abdominal contents is noted, an abdominal binder with sterile towels soaked in saline can be use to replace abdominal contents and temporize the situation. Broad-spectrum antibiotics generally are recommended to minimize ensuing peritonitis.

The final goal of treatment is closure. For critically ill patients with significant edema, temporarily maintaining anterior abdominal wall integrity until a patient is stable enough to tolerate a definitive operative closure is reasonable. Fascial closure under general anesthesia is performed after sufficient dÃ©bridement of necrotic or infected tissue. An interrupted mass closure using a no. 2 permanent suture typically is recommended. However, if primary closure is under significant tension, a synthetic mesh bridge may be required. If the subcutaneous wound is left open, wet-to-dry dressing changes may be performed until the decision has been made to proceed with a delayed primary closure or allow secondary intention to compete the process (Cliby, 2002).

INTRAOPERATIVE CONSIDERATIONS: INTRODUCTION

Although conservative medical management of most gynecologic conditions is preferred, many conditions are not amenable to this approach, and surgery is required. Successful gynecologic surgery is directed at treatment of underlying pathology and uses techniques that maximize tissue healing and patient recovery. During any procedure, intraoperative complications may be encountered, and surgeons should be familiar with these challenges and their management.

ANESTHESIA SELECTION

Many anesthetic options are available for patients undergoing gynecologic procedures. Paracervical blockade using local anesthetic agents may be used alone or more commonly, with conscious sedation prior to dilatation and curettage or hysteroscopy. However, in patients requiring a greater degree of anesthesia, general anesthesia or regional epidural or spinal techniques typically are used.

The delivery of these anesthetic techniques should be provided by clinicians who are skilled with their placement and are capable of managing their side effects. Thus, in general, paracervical blockade and intravenous sedation may be provided by gynecologists. General, epidural, and spinal anesthesia typically are delivered and managed by anesthesiology staff.

The selection of anesthesia for gynecologic surgery is complex. Clinical factors such as the procedure planned, extent of disease, and patient comorbidities weigh heavily in the decision process. Moreover, personal preferences of the patient, anesthesiologist, and surgeon influence choice. Lastly, the providing hospital or clinic may further define options based on their practicing norms and availability of personnel or equipment. For example, an outpatient gynecology clinic may have supporting personnel and equipment sufficient for paracervical blockade or intravenous conscious sedation but may lack sophisticated equipment or expertise required for regional or general anesthesia.

In all cases, both the anesthesia provider and the surgeon should be prepared for potential problems. Cases using paracervical blockade may be complicated by inadequate levels of anesthesia or conversely, by anesthetic toxicity. Conscious sedation also may fail to provide adequate analgesia or alternatively, may lead to respiratory depression. Difficult patient intubation may complicate general anesthesia, and regional anesthetic procedures may lead to higher than anticipated levels of blockade and respiratory muscle dysfunction. Thus, no procedure is free of potential risk, and contingency plans for each should be in place.

Paracervical Block

ANATOMY

The cervix, vagina, and uterus are richly supplied by nerves of the uterovaginal plexus. (see Fig. 38-23B). Also known as *FrankenhÃ¤user plexus,* this plexus lies within the connective tissue lateral to the uterosacral ligaments. For this reason, paracervical injections are most effective if placed immediately lateral to the insertion of the uterosacral ligaments into the uterus (Rogers, 1998).

TECHNIQUE

Injection of divided doses may be given at 4 and 8 o'clock at the cervical base (Figs. 40-1 and 40-2). Alternatively, injections may be placed at 3, 6, 9, and 12 o'clock sites. However, this increased number of sites appears not to improve analgesic effects (Glantz, 2001).

FIGURE 40-1

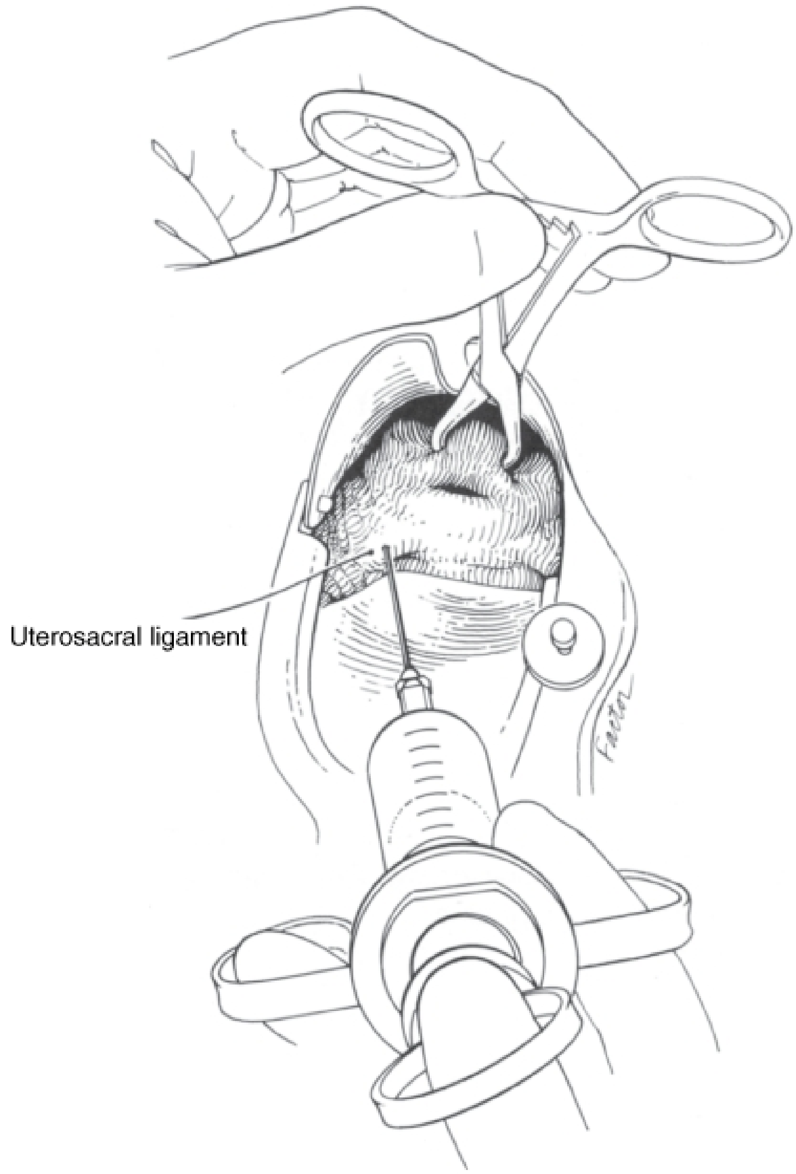
Abdominal view of a paracervical block. Local anesthetics are infiltrated near sensory innervation of the cervix, which lies lateral to the uterosacral ligament. *(From Penfield, 1986, with permission.)*

FIGURE 40-2



Source: Schorge JO, Schaffer JI, Halvorson LM, Hoffman BL, Bradshaw KD, Cunningham FG: *Williams Gynecology*: http://www.accessmedicine.com

Vaginal approach to the injection of local anesthetics into cervical base at 4 and 8 o'clock. *(From Penfield, 1986, with permission.)*

In most cases, total doses of 10 mL of 0.25-percent bupivacaine, 1-percent mepivicaine, or 1- or 2-percent lidocaine may be administered (Table 40-1) (Cicinelli, 1998; Hong, 2006; Lau, 1999). However, specific calculation of a maximum safe dose for each patient before injection is recommended (Dorian, 2005). The toxic dose of lidocaine approximates 4.5 mg/kg. Thus, for a 50-kg woman: 4.5 mg/kg $\times$ 50 kg = 225 mg.

Table 40-1 Characteristics of Local Anesthetics				
Drug	**Available Concentrations, %**	**Maximum, mg/kg**	**Maximum Dose with Epinephrine Combined, mg/kg**	**Duration, h**
Moderate-duration				
Lidocaine	0.5, 1, 2	4.5	7	0.5â€“1
Mepivicaine	0.5, 1	4	7	0.75â€“1.5
Prilocaine	0.5, 1	7	8.5	0.5â€“1.5
Long-duration				
Bupivicaine	0.25, 0.5	2.5	3	2â€“4
Etidocaine	0.5, 1	4	5.5	2â€“3

For any drug solution, 1-percent = 10 mg/mL. Thus, if a 1-percent lidocaine solution is used for a 50-kg woman, the calculated allowed amount would be: 225 mg Ã· 10 mg/mL = 22.5 mL.

Anesthesia is presumed to result from pharmacologic nerve conduction blockade by a local anesthetic agent (Chanrachakul, 2001). Each drug has a different recovery time based on individual solubility and tissue binding. Moreover, addition of epinephrine to these solutions leads to local vasoconstriction, which enhances the quality of analgesia, prolongs the duration of action, and decreases toxicity. Return of neural function is spontaneous as the drug is metabolized.

Alternatively, injection itself may have an immediate anesthetic effect by swelling surrounding tissue and exerting mechanical pressure on nerves to disrupt neural transmission. In support of this, similar pain scores were noted in women undergoing elective abortion whether a procedure began immediately after paracervical injection or following a several-minute delay to allow pharmacologic blockade (Phair, 2002; Wiebe, 1995).

USAGE

Paracervical block is used most commonly during first-trimester pregnancy evacuation but also has been used prior to cervical ablative or excisional procedures, transvaginal sonographically guided oocyte retrieval, and in-office hysteroscopy.

Often, paracervical block is combined with nonsteroidal anti-inflammatory drugs (NSAIDs) or intravenous conscious sedation or both. Conscious sedation may be achieved with several agents, but intravenous midazolam combined with fentanyl is used frequently (Lichtenberg, 2001). Table 10-2 lists therapeutics doses of NSAIDs.

Table 40-2 The Lumbosacral Plexus Nerve Plexus (L1-S4)			
Nerve	**Origin**	**Motor Function**	**Sensory Function**
Ilioinguinal	L1	None	Inferior abdominal wall, mons pubis, labia majora
Iliohypogastric	L1	None	Inferior abdominal wall, upper lateral gluteal region
Genitofemoral	L1-2	None	Labia majora, anterior superior thigh
Lateral femoral	L2-3	None	Anterolateral thigh
Cutaneous femoral	L2-4	Hip flexion, adduction; Knee extension	Anterior and medial thigh, medial calf
Obturator	L2-4	Thigh adduction, lateral rotation	Superomedial thigh
Pudendal	S2-4	Muscles of perineum; External anal and urethral sphincters	Perineum
Sciatic	L4-S3		
Common peroneal	L4-S2	Knee flexion; Foot dorsiflexion, eversion; Toe extension	Lateral calf, foot dorsum
Tibial	L4-S3	Thigh extension; Knee flexion; Foot plantar flexion; inversion	Foot plantar surface, toes

TOXICITY

Increased doses of local anesthetics may lead to clinically significant conduction blockade within the central nervous system (CNS) and heart. Signs range from drowsiness, tinnitus, perioral tingling, and visual disturbances to confusion, seizure, coma, and ventricular arrhythmia. In monitoring patients, surveillance for the subtle symptoms of CNS toxicity is important because the therapeutic-to-toxic ratios are often narrow with these agents.

When toxicity develops, cardiac effects are potentiated by acidosis, hypercapnia, and hypoxia. Thus, treatment of toxicity typically includes intravenous access, adequate oxygenation, and seizure control. A benzodiazepine such as diazepam given intravenously is effective anticonvulsant therapy (Naguib, 1998). For treatment, diazepam, 2 mg/min, is administered until seizures stop or a total dose of 20 mg is delivered.

Intrauterine Instillation

Injection of local anesthetic solutions through a catheter into the uterine cavity has been reported to lower pain scores in women undergoing in-office hysteroscopy or endometrial biopsy (Cicinelli, 1997; Trolice, 2000). The presumed mechanism is anesthetic blockade of nerve endings within the endometrial mucosa. Studies have used 5-mL doses of 2-percent lidocaine or of 2-percent mepivicaine. Edleman and co-workers (2004, 2006) combined instillation of 5 mL of 4-percent lidocaine with paracervical blockade for first-trimester abortion procedures. However, a significant number of women reported symptoms attributed to lidocaine toxicity, including numbness, tingling, and ear ringing.

PATIENT POSITIONING

Anesthetized patients who undergo prolonged gynecologic procedures are at risk for development of peripheral neuropathy of their upper or lower extremities. These neuropathies are uncommon, and cited incidences approximate 2 percent of gynecologic cases

(Cardosi, 2002). Neurologic deficits typically are mild, transient, and resolve spontaneously. However, infrequently, prolonged or permanent disability may result.

During gynecologic surgery, lower extremity injuries may involve nerves of the lumbosacral plexus (Table 40-2). In most cases, peripheral neuropathy follows improper placement of self-retaining retractors, radical pelvic dissection, or improper patient positioning, especially in the lithotomy position. Mechanisms of injury include surgical nerve transection, rupture following increased stretch, or nerve ischemia. Ischemia may result from compression of perineural vessels during prolonged or pronounced nerve stretch or compression.

Although any patient may develop postoperative neuropathy, higher rates have been noted in patients who smoke, who have anatomic abnormalities, or who are thin, diabetic, or alcoholic. Use of self-retaining retractors and prolonged surgical duration are additional risks (Warner, 1994).

Symptoms reflect functional loss of the affected nerve. Motor loss typically manifests as muscle weakness, whereas sensory loss may be noted as anesthesia, paresthesia, or pain in the nerve's sensory distribution (Fig. 40-3). Therefore, a detailed neurologic examination allows clinical identification of most peripheral neuropathies. Electrodiagnostic testing is indicated if motor function is diminished, but this lacks adequate sensitivity in cases of sensory loss (Knockaert, 1996). Generally, electromyography is most useful after a 2- to 3-week delay to permit denervational changes to fully develop within the affected muscles (Winfree, 2005).

FIGURE 40-3

Peripheral nerves and their corresponding areas of sensory innervation. *(From Ducic, 2006, with permission.)*

Treatment will vary depending on whether motor or sensory function is affected. If motor function is impaired, neurologic consultation is warranted. Physical therapy should begin immediately to minimize contracture and muscle atrophy. Alternatively, for those with only mild sensory losses, observation for return of function is reasonable. For those with pain, treatments may include serial trigger point injection with local anesthetics; oral analgesics; biofeedback; and gabapentin. If conservative options fail to bring sufficient relief, neurectomy ultimately may be required for those with chronic pain (Madura, 2005).

Laparotomy

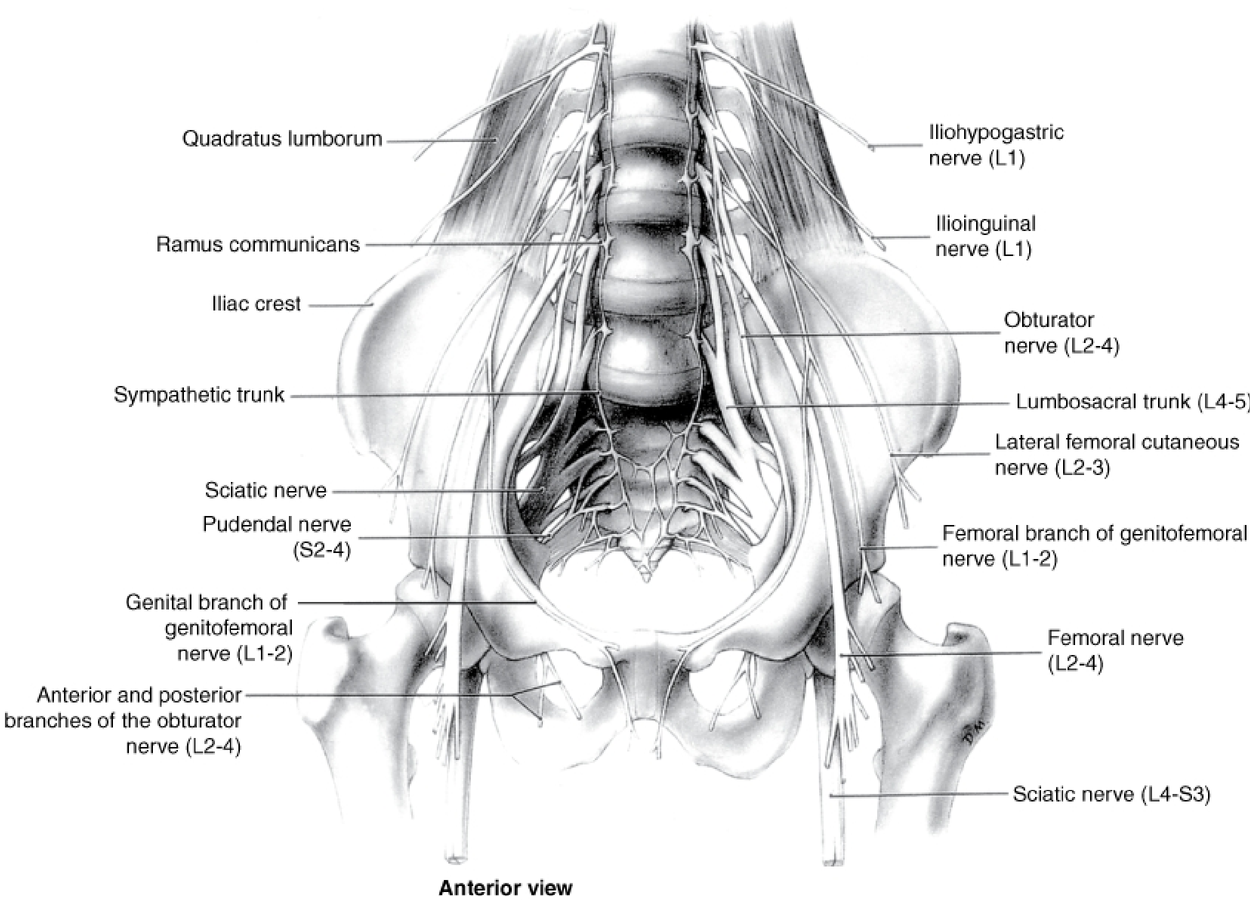
Nerve injury may occur at the time of laparotomy and more commonly results from poor retractor placement, wide transverse abdominal wall incisions, and extensive dissections at the pelvic sidewall.

SELF-RETAINING RETRACTORS

Femoral Nerve Injury

The femoral nerve perforates the psoas muscle early in its course to provide motor function to the iliac, sartorius, and quadriceps muscles and sensory function to the anteromedial thigh and medial leg (Fig. 40-4). Before exiting the pelvis, this nerve passes medially beneath the inguinal ligament to enter the femoral triangle lateral to the femoral artery and vein. This nerve can be compressed anywhere along its course but is particularly susceptible within the body of the psoas muscle and at the inguinal ligament.

FIGURE 40-4

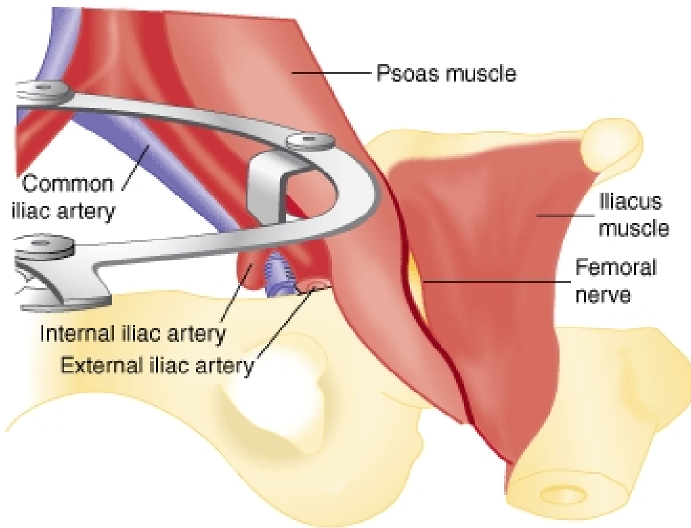


Source: Schorge JO, Schaffer JI, Halvorson LM, Hoffman BL, Bradshaw KD, Cunningham FG: *Williams Gynecology*: http://www.accessmedicine.com

Nerves of the lumbosacral nerve plexus. *(From Irvin, 2004, with permission.)*

Improper placement of a self-retaining retractor is the most common cause of surgical femoral nerve injury, and rates following abdominal hysterectomy may reach 10 percent (Goldman, 1985; Kvist-Poulsen, 1982). Injury results from compression of the psoas muscle and femoral nerve by retractor blades, and increasing blade size has been implicated with increasing rates of injury (Fig. 40-5) (Kvist-Poulsen, 1982).

FIGURE 40-5



Source: Schorge JO, Schaffer JI, Halvorson LM, Hoffman BL, Bradshaw KD, Cunningham FG: *Williams Gynecology*: http://www.accessmedicine.com

Lateral blade of a self-retaining retractor can compress the psoas major muscle and femoral nerve against the pelvic sidewall. *(From Irvin, 2004, with permission.)*

Women with femoral neuropathy may display impaired motor function with weakness or inability to flex the hip or extend the knee. The patellar reflex is usually absent. Impaired sensory function is characterized by paresthesia over the anteromedial thigh and medial calf.

In prevention, lateral retractor blades should be selected and positioned such that only the rectus abdominis muscle and not the psoas muscle is retracted (Chen, 1995). For thin patients, folded laparotomy sponges may be placed between the retractor rim and skin to elevate blades away from the psoas muscle.

Genitofemoral Nerve Injury

The genitofemoral nerve pierces the medial border of the psoas muscle and traverses below the peritoneum on this muscle's surface. Above the inguinal ligament, it divides into genital and femoral branches. The femoral branch follows the external iliac artery, continues behind the inguinal ligament, and exits through the fascia lata to provide sensory function to the femoral triangle. The genital branch enters the inguinal canal to supply sensation to the labia majora and mons pubis. Similar to the femoral nerve, the genitofemoral nerve may suffer injury with compression of the psoas muscle, and sensory symptoms follow the distribution of the nerve (see Fig. 40-3) (Murovic, 2003). In addition, this nerve may be injured during removal of a large pelvic mass adherent to the sidewall or during external iliac lymph node dissection (Irvin, 2004).

Lateral Femoral Cutaneous Nerve Injury

This nerve appears at the lateral border of the psoas major muscle just above the crest of the ilium. It courses obliquely across the anterior surface of the iliac muscle and dips beneath the inguinal ligament laterally as the nerve exits the pelvis. The lateral

femoral cutaneous nerve may be compressed as the nerve courses along the pelvic wall (Aszmann, 1997). Sensory symptoms extend over the anterolateral hip and thigh. Painful neuropathy specifically involving the lateral femoral cutaneous nerve carries the specific name *meralgia paresthetica* .

TRANSVERSE INCISIONS

Nerve injury during transverse abdominal entry is common. It typically involves the ilioinguinal and iliohypogastric nerves or less frequently, branches of the genitofemoral nerve. The ilioinguinal and iliohypogastric nerves emerge through the internal oblique muscle approximately 2 to 3 cm inferomedial to the anterosuperior iliac spine (Whiteside, 2003). The iliohypogastric nerve extends a lateral branch to innervate the lateral gluteal skin. An anterior branch reaches horizontally toward the midline and runs deep to the external oblique muscle. Near the midline, this nerve perforates the external oblique muscle and becomes cutaneous to innervate the superficial tissues and skin in the region above the symphysis pubis (see Fig. 38-4). The ilioinguinal nerve extends medially to enter the inguinal canal and innervates the lower abdomen, labia majora, and upper thigh.

These are sensory nerves, and fortunately, most skin anesthesia or paresthesias that follow their injury resolves with time. For this reason, injuries frequently are underreported by both patients and clinicians.

Pain, however, in some cases may result and may begin immediately following surgery or many years later. It is usually sharp and episodic and radiates to the upper thigh, labia, or upper gluteal region. Later, sensations may become chronic and burning (Ducic, 2006).

Diagnosis can be confirmed with trigger point injection of local anesthetics. Sippo and colleagues (1987) describe injection of a solution containing a 2:1 ratio of 0.5-percent bupivacaine and 1-percent lidocaine. The needle is inserted at a point 1 cm inferomedial to the anterosuperior iliac spine to reach the depth of the external oblique muscle. Solution is injected medially in a fan-shaped distribution. Pain relief following nerve blockade is diagnostic.

PELVIC SIDEWALL DISSECTION

Lymph node dissection, tumor excision, or endometriosis resection performed at the pelvic sidewall may injure the obturator or genitofemoral nerves. Moreover, the obturator nerve also can be injured during dissection within the space of Retzius during urogynecologic procedures (see Fig. 38-25).

Obturator Nerve Injury

This nerve pierces the medial border of the psoas muscle and extends anteriorly along the lesser wall of the pelvis. The obturator nerve exits through the obturator foramen to supply adductor muscles of the thigh and the obturator externus muscle, which rotates the thigh laterally. Sensory innervation covers the superomedial thigh. Women with obturator neuropathy display weakness of hip adduction and external rotation and sensory symptoms extending over the medial thigh (Vasilev, 1994).

Dorsal Lithotomy

This surgical position is used for vaginal, laparoscopic, and hysteroscopic surgeries. It is modified and described as high, standard, or low lithotomy positions (Fig. 40-6). Dorsal lithotomy may be associated with injury to several nerves derived from the lumbosacral plexus, including the femoral, sciatic, and peroneal nerves. For example, compression and ischemic injury of the femoral nerve beneath the rigid inguinal ligament can follow prolonged sharp flexion, abduction, and external hip rotation in dorsal lithotomy (Fig. 40-7) (Ducic, 2005; Hsieh, 1998). Ideal positioning as shown can minimize these injuries.

FIGURE 40-6

SCIATIC NERVE

Derived from the lower sacral plexus, this nerve exits the pelvis through the greater sciatic foramen. It extends down the posterior thigh and branches into the tibial nerve and common peroneal nerve above the popliteal fossa. The sciatic and common peroneal nerves are anatomically fixed at the sciatic notch and head of the fibula, respectively. Thus stretch injury to the sciatic nerve can develop if a patient's hips are placed in sharp flexion or pronounced external rotation or both. Moreover, even an appropriately positioned patient may be injured if a surgical assistant during vaginal surgery leans against the thigh and creates extreme hip flexion.

The sciatic nerve contains tibial and common peroneal divisions, and injury may reflect impaired function of the entire sciatic nerve or only the common peroneal division. If the entire nerve is injured, impaired hip extension, knee flexion, and foot flexion is seen. In addition, sensory loss of the foot may be noted (McQuarrie, 1972). If only the common peroneal division is injured, then losses reflect those described in the next section.

COMMON PERONEAL NERVE

Now also termed the *common fibular nerve,* the common peroneal nerve is a lateral branch of the sciatic nerve. From its origin above the popliteal fossa, this nerve crosses the lateral head of the fibula before it descends down the lateral calf. At the lateral fibular head, this nerve is at risk for compression against leg stirrups. Therefore, patient positioning that avoids pressure at this point or the addition of cushioned padding is warranted (Philosophe, 2003).

Injury to the common peroneal nerve may have motor and sensory consequences. An inability to flex or evert the foot, or extend the toes may be noted as a "foot drop" with walking. Sensory loss encompasses the foot dorsum and anterolateral leg (Tikoo, 1994).

SURGICAL INCISIONS

In women for whom laparotomy is selected, an ideal abdominal incision allows rapid entry, affords adequate exposure, permits early ambulation, promotes strong wound healing, does not compromise pulmonary function, and maximizes cosmetic results. These criteria should form the foundation in choosing the best incision for each patient. In gynecology, entry into the abdomen typically is achieved using a midline vertical incision or one of three transverse incisions, the Pfannenstiel, Cherney, or Maylard incisions.

Midline Vertical Incisions

These incisions are used frequently when access to the upper abdomen and generous operating space are required. They can be extended up and above the umbilicus and thus, are preferred when the preoperative diagnosis is uncertain. Moreover, simple midline anatomy allows quick entry into the abdomen and low rates of neurovascular injury to the anterior abdominal wall (Greenall, 1980; Lacy, 1994). Moreover, because of decreased midline vascularity, Nygaard and Squatrito (1996) recommended this incision in patients who have coagulopathy, decline transfusion, or are administered systemic anticoagulation.

Its greatest disadvantage stems from increased tension on the incision when abdominal muscles contract. For this reason, compared with transverse incisions, midline vertical incisions are associated with higher rates of fascial dehiscence and hernia formation and poorer cosmetic results (Grantcharov, 2001; Kisielinski, 2004).

Transverse Incisions

These incisions are used commonly in benign gynecologic surgery and provide several advantages. They follow Langer lines of skin tension and thus offer superior cosmetic results. They also carry low rates of incisional hernia (Luijendijk, 1997). In addition, their placement in the lower abdomen is associated with decreased postoperative pain and improved pulmonary function compared with midline vertical incisions. Of transverse incisions, Pfannenstiel incision typically is the simplest to perform and for this reason is

selected most commonly.

Despite these advantages, limitations are noted with transverse incisions. These incisions limit access to the upper abdomen, and they offer smaller operating space compared with midline incisions. This is especially true of the Pfannenstiel incision and results from narrowing of the surgical field by intact rectus abdominis muscle bellies, which straddle the incision (see Section 41-2, Pfannenstiel Incision).

Consequently, Cherney and Maylard incisions were developed to overcome this restriction, and to some degree, they do improve exposure (see Sections 41-3, Cherney Incision and 41-4, Maylard Incision). The Cherney incision releases the rectus abdominis muscle at its inferior tendinous insertion. This approach affords greater exposure of pelvic organs as well as access to the space of Retzius. Its use therefore is considered when such operating exposure is needed.

Alternatively, the Maylard incision transects the rectus abdominis muscle and provides greater operative exposure and maneuvering space. However, it is technically more difficult to perform because isolation and ligation of the inferior epigastric arteries are required. The incision is used infrequently because of concerns regarding greater postoperative pain, decreased abdominal wall strength, longer operating times, and increased febrile morbidity. Randomized studies, however, have not supported these concerns (Ayers, 1987; Giacalone, 2002).

Incision Creation

Entry into the abdomen begins with scalpel incision of the skin, and scars should be excised to improve wound healing and cosmetic results. Although an electrosurgical blade may be used to incise the skin, faster healing and improved appearance in general follow scalpel incision (Hambley, 1988; Singer, 2002b). For the remaining layers, scalpel or electrosurgical blade may be selected, and investigations have found no differences in short- or long-term wound healing if either is chosen (Franchi, 2001). However, in evaluating surgical bleeding and postoperative pain, Jenkins (2003), in his review, noted an advantage with electrosurgical blade use.

WOUND CLOSURE

Following laparotomy, closure of a laparotomy incision must address the peritoneum, fascia, subcutaneous layer, and skin. Wound closure may be broadly categorized as either primary or secondary. With primary closure, materials are used to approximate tissue layers. In secondary closure, wound layers remain open and heal by a combination of contraction, granulation, and epithelialization. Secondary closure is used infrequently in gynecologic surgery and typically is indicated if tissues planned for closure contain significant infection. Thus, most wounds are closed primarily, as discussed below.

Optimal closure of laparotomy is the subject of much debate. Most data on the subject stem from general surgery studies on midline abdominal incision closure and from obstetric investigations of cesarean delivery technique. Ideally, closure avoids wound infection, dehiscence, and hernia or sinus tract formation yet minimizes patient discomfort.

Peritoneum

Neither visceral nor parietal peritoneum requires suturing because this layer typically regenerates within days following surgery (Lipscomb, 1996). Several studies have shown that nonclosure of the peritoneum compared with closure decreases operating time without increasing adhesion formation, wound complications, or infection (Franchi, 1997; Gupta, 1998; Tulandi, 1988).

Adhesions may commonly develop between the peritoneum and adjacent organs following surgery. Scarring can be reduced by attention to delicately handling tissues, achieving hemostasis, and by minimizing tissue ischemia, infection, and foreign-body reaction (Practice Committee of the American Society of Reproductive Medicine, 2007)

Fascia

Thus, in many cases, the first tissue closed is fascia. Many studies have supported the use of a continuous running-stitch closure of abdominal incisions compared with interrupted closure of the fascia (Colombo, 1997; Orr, 1990; Shepherd, 1983). Continuous closer usually is faster and associated with comparable rates of dehiscence, wound infection, and hernia formation. Suture material selection tends to favor delayed-absorbable suture compared with nonabsorbable. Delayed-absorbable sutures appear to afford

adequate wound support yet lead to less pain and lower rates of sinus tract formation (Carlson, 1995; Leaper, 1977; Wissing, 1987). Sutures should be placed approximately 1 cm apart and approximately 1 cm from the fascial edge. Stitches should appose fascial edges and allow tissues to swell postoperatively without cutting through fascia or causing avascular necrosis.

Subcutaneous Adipose Layer

Collections of blood and fluid serve as potential accelerants to bacterial growth. For this reason, investigators have addressed the use of subcutaneous layer suture closure or drains as a means to decrease hematoma and seroma collections. Most studies have investigated cesarean deliveries rather than gynecologic surgeries but have found no advantage to either practice in those with layers less than 2 cm thick. However, wound infection and fat thickness are the greatest risk factors for subcutaneous layer dehiscence (Soper, 1971; Vermillion, 2000). For patients with subcutaneous layers 2 cm or more thick, closing the subcutaneous layer has been shown to be effective (Gallup, 1996; Guvenal, 2002; Naumann, 1995).

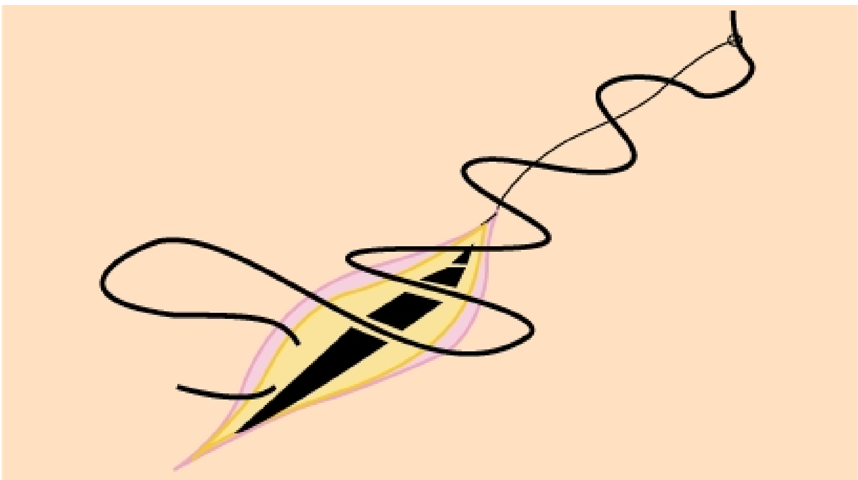
Skin

Skin may be closed effectively with staples, subcuticular suturing, adhesive wound tape, or tissue adhesive. Thus, in most instances, this layer is closed according to surgeon preference.

SUBCUTICULAR SUTURING

The running subcuticular suture is placed by taking horizontal bites through the papillary dermis on alternating sides of the wound using absorbable suture (Fig. 40-8). Advantages include decreased cost, effective skin approximation, and no required suture removal. Of skin closure techniques, however, this method typically requires the greatest amount of time and technical expertise.

FIGURE 40-8



Source: Schorge JO, Schaffer JI, Halvorson LM, Hoffman BL, Bradshaw KD, Cunningham FG: *Williams Gynecology*: http://www.accessmedicine.com

During subcuticular suturing, stitches are placed with a needle horizontal to the dermis. Suturing is advanced by sequentially piercing just below the dermis on alternating sides. The spot that the first stitch exits the subcutis marks the site along the wound length that the needle should enter on the opposite side.

TOPICAL SKIN ADHESIVES

Octyl-2-cyanoacrylate (Dermabond, Ethicon, Somerville, NJ) is a topical tissue adhesive that is applied as a liquid and polymerizes to a firm, pliable film that binds to epithelium and bridges wound edges (Fig. 40-9). Appropriate for closure of skin incisions that carry minimal tension such as laparoscopy trocar or transverse laparotomy incisions, tissue adhesives achieve similar cosmetic results as traditional sutures (Blondeel, 2004; Singer, 2002a).

FIGURE 40-9

Source: Schorge JO, Schaffer JI, Halvorson LM, Hoffman BL, Bradshaw KD, Cunningham FG: *Williams Gynecology*: http://www.accessmedicine.com

Application of topical skin adhesive to incision. Adhesive should be placed over apposed skin edges. Application should extend out approximately 0.5 cm laterally from the incision. *(Courtesy of Ethicon, Somerville, NJ.)*

Following approximation of deeper incision layers, the adhesive is applied in three thin layers above apposed skin edges. The adhesive extends at least Â½ cm on each side of the apposed wound edges. Attention is required to avoid placement of the liquid between skin edges because the adhesive may retard healing (Quinn, 1997). Although 30 seconds between layers for drying is required, application is fast. Moreover, adhesives create their own dressing and appear to afford some antibacterial protection (Bhende, 2002). Suture or staple removal is avoided, and the adhesive sloughs in 7 to 10 days. Showering and gentle washing of the site are allowed, but swimming is discouraged. Petroleum-based products on the wound can decrease adhesive tensile strength and should be avoided.

ADHESIVE WOUND TAPE

The primary indication for tape closure is a superficial straight laceration under little tension. Thus, it is appropriate for closure of laparoscopy trocar incision sites or laparotomy incisions in which deep layer closure has brought skin edges into close proximity.

Tissue closure is fast, inexpensive, and associated with high patient satisfaction. Tapes typically are removed by the patient 7 to 10 days following surgery.

Prior to application, skin edges should be thoroughly dry for proper adhesion. Adhesive tape strips are applied in a parallel, nonoverlapping fashion after coating the entire application area with adjuvant adhesive such as tincture of benzoin (Katz, 1999). Tape may not be appropriate for a wet or oozing wound, for concave surfaces such as the umbilicus, for areas of significant tissue tension, or for areas of marked tissue laxity. Moreover, tape may separate prematurely in approximately 3 percent of cases. Importantly, skin blistering may develop if tape is stretched excessively across the wound (Lammers, 2004; Rodeheaver, 1983).

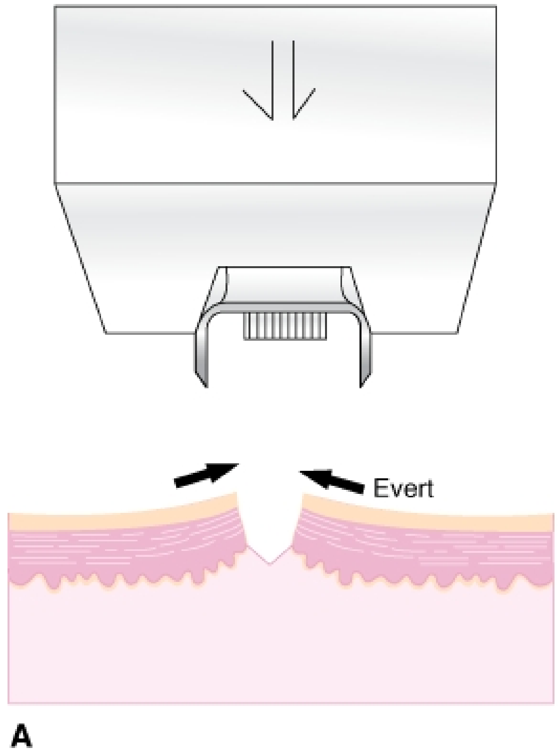
STAPLES

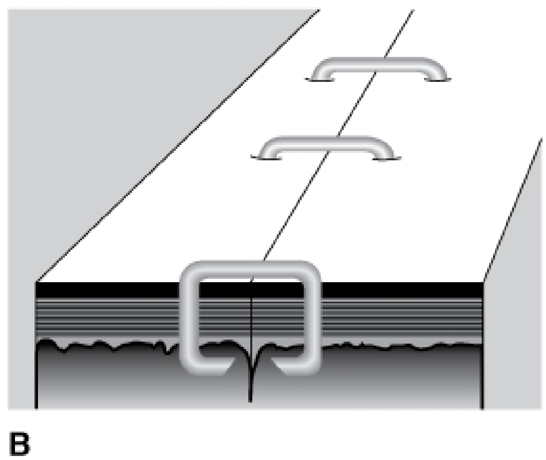
Automatic stapling devices are used commonly for surgical incisions and are favored because of their fast application and secure wound closure. However, they do not allow as meticulous a closure as sutures, and wounds requiring accurate approximation of tissue are not ideal candidates for staple closure (Singer, 1997). Staples also may be uncomfortable, may be associated with discomfort during removal, and require the patient to return for removal.

Before stapling, the wound edges should be everted, preferably by a second operator. The assistant precedes the operator along the wound and everts the wound edges with forceps. If the edges of a wound invert, or if one edge rolls under the opposite side, a poorly formed, deep, noticeable scar will result. Additionally, pressing too hard against the skin surface with the stapler should be avoided to prevent placing the staple too deeply and causing ischemia within the staple loop. When placed properly, the crossbar of

the staple is elevated a few millimeters above the skin surface (Fig. 40-10) (Lammers, 2004).

FIGURE 40-10





A. Illustration of correct staple placement. **B.** Approximately 2 to 3 mm should lie between the skin and staple crossbar. Pressure created by burying the staple into the skin may cause wound edge ischemia or painful removal. *(From Edlich, 1979, with permission.)*

INSTRUMENTS

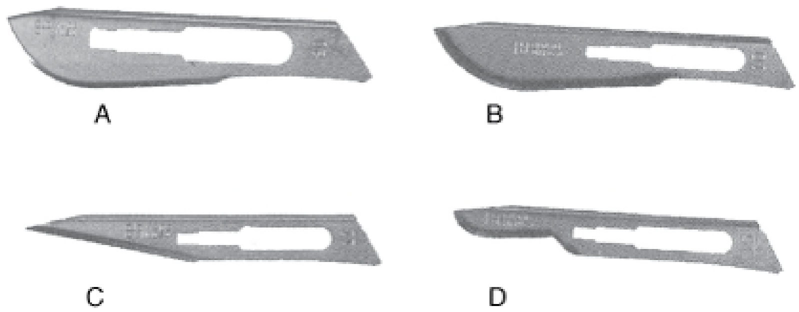
Surgical instruments have been designed to extend the capability of a surgeon's hands and thus are crafted to retract, cut, grasp,

and clear the operative field. Tissue types encountered in gynecologic surgery vary. Accordingly, so too do the size, fineness, and strength of the tools used.

Scalpel and Blades

Typical surgical blades used in gynecologic surgery are pictured in Figure 40-11 and include number 10, 11, 15, and 20 blades. Function follows form, and larger blades are used for coarser tissues or larger incisions, whereas a no. 15 blade is selected for finer incisions. The acute angle and pointed tip of a no. 11 blade can easily incise tough-walled abscesses for drainage, such as those of the Bartholin gland. During abscess drainage, the blade is drawn up and through the skin in a forward-sweeping arc.

FIGURE 40-11

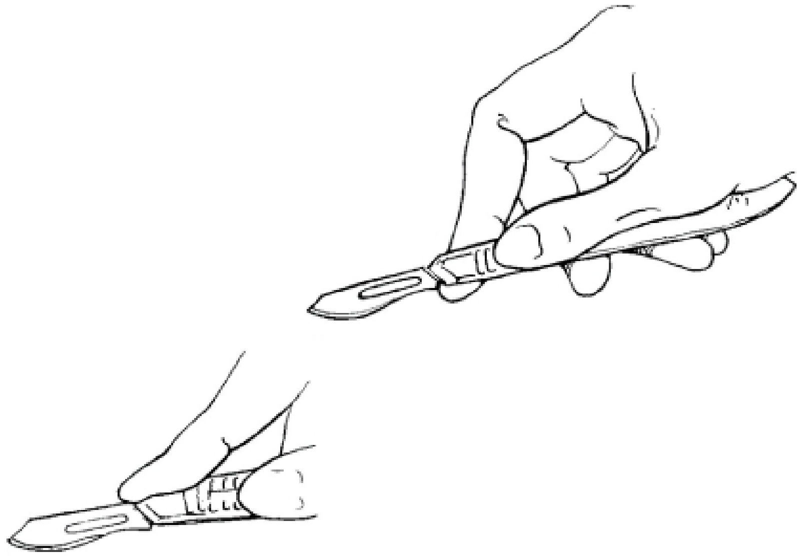


Source: Schorge JO, Schaffer JI, Halvorson LM, Hoffman BL, Bradshaw KD, Cunningham FG: *Williams Gynecology*: http://www.accessmedicine.com

Photograph of surgical blades commonly used in gynecology. **A.** No. 20. **B.** No. 10. **C.** No. 11. **D.** No. 15. *(From Hurt, 2002, with permission.)*

With correct scalpel grasping, a surgeon can direct blade movement. Fingers may be positioned either to straddle the scalpel or to hold it as a pencil (Fig. 40-12). Incision should be made with the belly of the blade, and it is positioned perpendicular to the skin to avoid skin edge beveling. In creating long incisions such as those of the skin, a surgeon's arm moves as a smooth unit, with motion originating at the shoulder. Even pressure leads to uniform incision depth.

FIGURE 40-12



Source: Schorge JO, Schaffer JI, Halvorson LM, Hoffman BL, Bradshaw KD, Cunningham FG: *Williams Gynecology*: http://www.accessmedicine.com

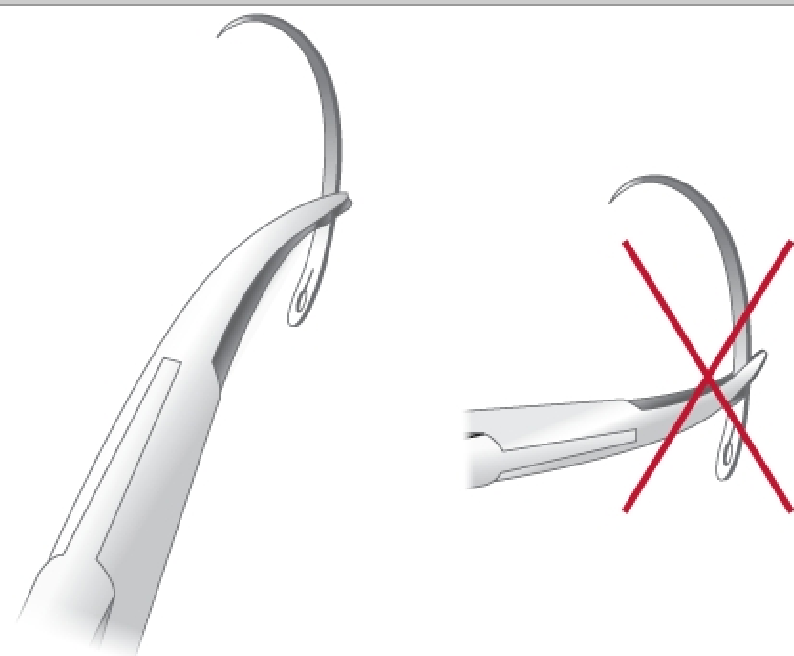
A. Scalpel is held as one would a pencil, and movement is directed by the thumb and index finger. **B.** Scalpel is held between the thumb and third finger. The index finger exerts downward pressure, and the end of the blade is forced up against the thenar muscles of the hand. *(From Wind, 1987, with permission.)*

Needle Holders

Needle holders may be straight or curved, and commonly, one with straight, blunt jaws is chosen during routine tissue approximation and pedicle ligation. Needles ideally pierce tissues perpendicularly. Thus, in most cases, the needle holder grasps a needle at a right angle and at a site approximately two-thirds from the needle tip.

Alternatively, some needle holders, such as the Heaney needle holder, are curved and aid needle placement in confined or angled areas. If a curved holder is used, the needle is grasped similarly, and the inner curve of the holder faces the needle swage (Fig. 40-13).

FIGURE 40-13



Source: Schorge JO, Schaffer JI, Halvorson LM, Hoffman BL, Bradshaw KD, Cunningham FG: *Williams Gynecology*: http://www.accessmedicine.com

A. Correct grasp of a needle using a curved needle holder. **B.** Incorrect grasp. *(From Nichols, 1996, with permission.)*

Tissue Forceps

During suturing and dissection, tissues frequently are elevated or retracted with tissue forceps. Plain forceps have blunt, flat tips with shallow, fine grooves and are selected for atraumatic grasping in shallow incisions. Alternatively, a single-toothed Adson forceps provides a fine, precise grip. Its narrow, toothed tip, however, allows only a small area to be grasped and carries a greater risk of tissue tearing (Fig. 40-14). For stiffer, fibrous tissues, toothed forceps such as the Potts-Smith single-toothed forceps and Bonney forceps are preferred.

FIGURE 40-14

Tissue forceps. **A.** Adson. **B.** Bonney. **C.** DeBakey. **D.** Singley. *(From Hurt, 2002, with permission.)*

If precise elevation of delicate tissues is needed deeper in the pelvis, then narrow-tipped, finely grooved DeBakey forceps may be chosen. In contrast, the broader, shallow-grooved tips of Russian forceps and Singley forceps may be preferred if a broader or thicker area of tissue is manipulated.

Retractors

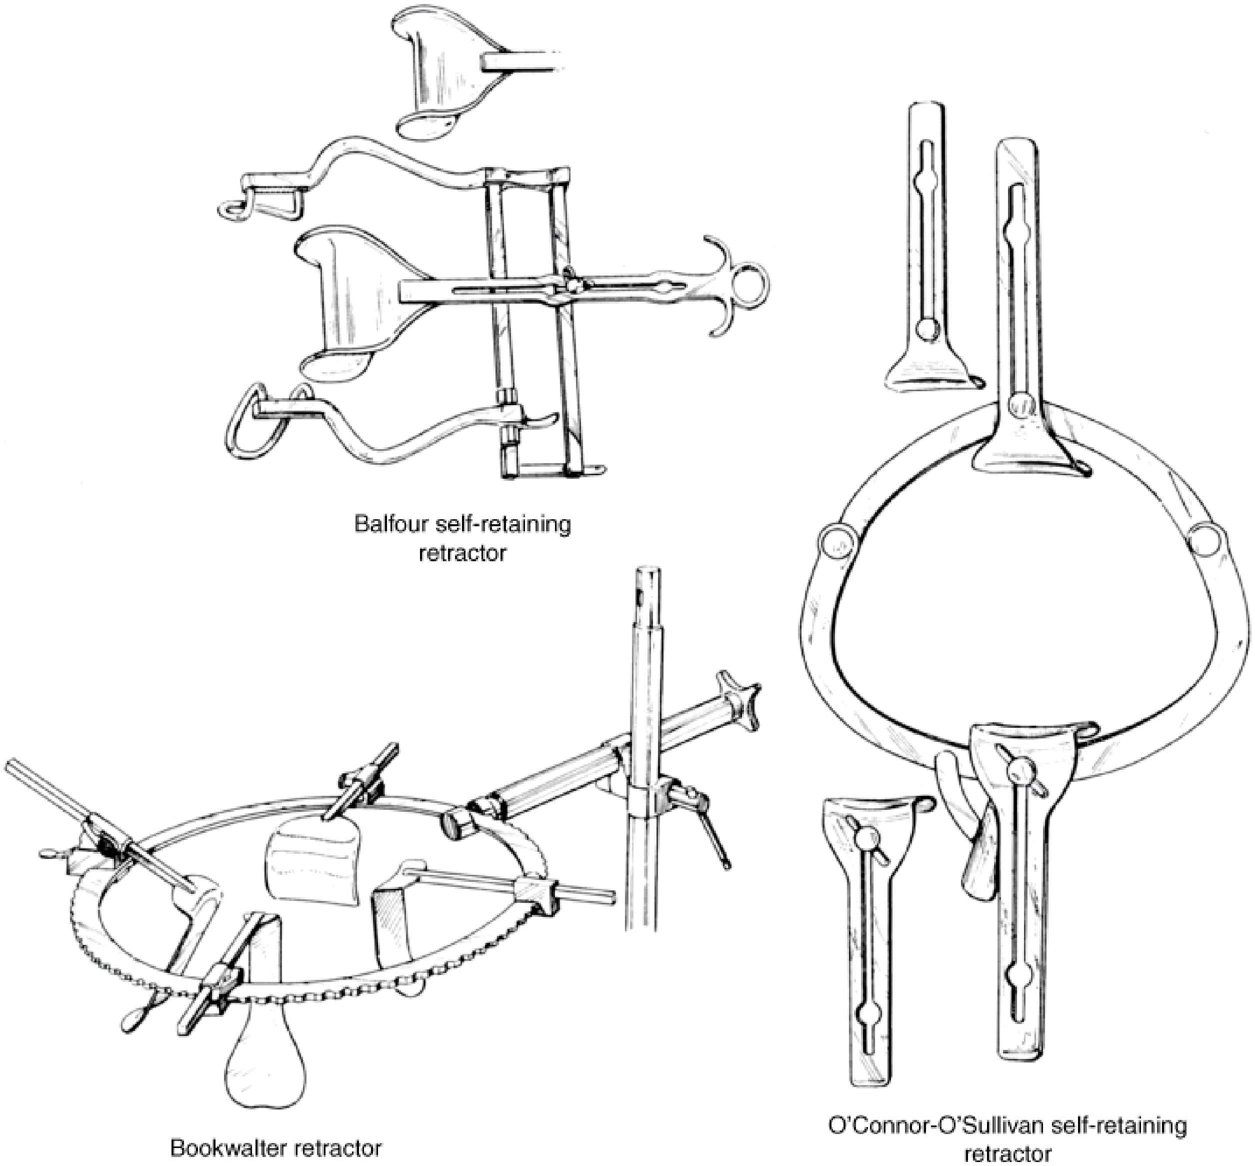
Clear visualization is essential during surgery, and retractors conform to body and organ angles to allow tissues to be pulled back from an operative field. In gynecology, retractors may be grouped broadly as self-retaining or hand-held and as abdominal or vaginal.

RETRACTORS USED IN ABDOMINAL SURGERY

Self-Retaining Retractors

Abdominal surgery often requires active participation of an assistant surgeon around a confined incision. Thus, retractors that by themselves hold abdominal wall muscles apart, termed *self-retaining,* are used commonly during laparotomy. Styles such as Balfour, Kirschner, and O'Connor-O'Sullivan contain four broad, gently curved blades and retract in four directions (Fig. 40-15). Blades pull the bladder caudally and the anterior abdominal wall muscles laterally and cephalad. Alternatively, ring-shaped retractors such as the Bookwalter and Denis Browne styles offer greater variability in the number and positioning of retractor blades. However, these usually require more time to assemble and place. With most of these styles, deep or shallow blades can be attached to the outer metal frame according to abdominal cavity depth. As discussed earlier, blades should be shallow enough to avoid compression of the femoral nerve within the psoas major muscle (Genitofemoral Nerve Injury).

FIGURE 40-15



Source: Schorge JO, Schaffer JI, Halvorson LM, Hoffman BL, Bradshaw KD, Cunningham FG: *Williams Gynecology*: http://www.accessmedicine.com

Abdominal self-retaining retractors. *(From Lipscomb, 1997, with permission.)*

Hand-Held Retractors

Hand-held retractors may be used in addition to or in place of self-retaining styles. These instruments allow retraction in only one direction but can be placed and repositioned quickly (Fig. 40-16). The Richardson retractor has a sturdy, shallow right-angled blade that can hook around an incision for abdominal wall retraction. Alternatively, Deaver retractors have a gentle arching shape and conform easily to the curve of the anterior abdominal wall. Compared with Richardson retractors, they offer increased blade depth and are used commonly to retract bowel, bladder, or anterior abdominal wall muscles. A Harrington retractor, also called a *sweetheart retractor,* has a broader tip that also effectively holds back bowel.

Hand-held retractors. **A.** Richardson. **B.** Deaver. **C.** Army-Navy. *(From Hurt, 2002, with permission.)*

In certain instances, such as during suturing of the vaginal cuff, a thin, deep retractor blade, termed a *malleable retractor,* may be required to retract or protect surrounding organs. Also called a *ribbon retractor,* this tool is a long, flexible metal strip that can be bent to conform to various body angles for effective retraction. Narrow and wider sizes are available. These also may be used to cover and protect underlying bowel from needle stick injury during abdominal wall closure.

For laparoscopy or minilaparotomy incisions, the preceding retractors are too large, and those with smaller blades such as the Army-Navy retractor or S-retractor are selected. S-retractors offer thinner, deeper blades, whereas sturdier blades of the Army-Navy style allow stronger retraction.

RETRACTORS USED IN VAGINAL SURGERY

Vaginal surgery requires separation of the vaginal walls, and several self-retaining models have been designed for this purpose. The Gelpi retractor has two narrow teeth that are placed against opposing lateral vaginal walls distally and is most appropriate for perineal procedures (Fig. 40-17). The Rigby retractor, with its longer blades, effectively separates lateral vaginal walls, whereas a Graves speculum holds apart anterior and posterior walls (see Fig. 1-4). An Auvard weighted speculum contains a long single blade

and ballasted end, which uses gravity to pull the posterior vaginal wall downward (Fig. 40-18).

Source: Schorge JO, Schaffer JI, Halvorson LM, Hoffman BL, Bradshaw KD, Cunningham FG: *Williams Gynecology*: http://www.accessmedicine.com

Auvard weighted vaginal speculum. *(From Hurt, 2002, with permission.)*

The degree of retraction offered by vaginal self-retaining retractors, however, at times may be limited. Therefore, hand-held retractors are required often to augment or replace these instruments. Hand-held retractors used in vaginal surgery include the Heaney right-angle retractor, the narrow Deaver retractor, and the Breitsky-Navaratil retractor (Figs. 40-19 and 40-20).

FIGURE 40-19

Breisky-Navratil retractors. *(From Hurt, 2002, with permission.)*

Additionally, during vaginal procedures, the cervix often must be manipulated. Lahey thyroid clamps offer a secure grip during

vaginal hysterectomy, but their several sharp teeth can cause significant trauma. These are therefore less than ideal in patients in whom the cervix will remain. In these patients, in whom curettage or laparoscopy is performed, a single-toothed tenaculum can afford a firm grip but with less cervical damage (Fig. 40-21).

FIGURE 40-21

Single-toothed tenaculum. *(From Hurt, 2002, with permission.)*

Scissors

Scissors are used commonly to divide tissues, and modification in blade shape and size allows their use in a variety of tissue textures (Fig. 40-22). For correct positioning, the thumb and fourth finger are placed within the instrument's rings, and the index finger is set against the crosspiece of the scissors for greater control.

FIGURE 40-22

Scissors. **A.** Curved Mayo. **B.** Metzenbaum. *(From Hurt, 2002, with permission.)*

The fine blades of Metzenbaum or iris scissors are used routinely to dissect or define natural tissue planes such as dividing thin adhesions or incising peritoneum or vaginal epithelium. During dissection, traction on opposing poles of the tissue to be dissected typically simplifies the process, and a small knick is often necessary to enter the correct tissue plane. The blades are closed and inserted between planes, following the natural curves of tissues being dissected (Fig. 40-23). The blades are opened and then withdrawn. After turning both wrist and blades 90 degrees, the surgeon reinserts the lower blade, and tissues are divided.

Metzenbaum scissors are used routinely in dissection. **A.** Dissection should proceed close to the organ surface and follows its natural curves. **B.** During development of tissue planes, the tips of closed Metzenbaum scissors are placed at the border between two tissues, and forward pressure is applied to advance the tips. **C.** The scissors are retracted and rotated 90 degrees. The lower blade is reinserted into the newly created tissue plane, and tissues are divided. *(From Wind, 1987, with permission.)*

Sturdier scissors such as curved Mayo scissors are used on thicker, denser tissues. Similarly, Jorgenson scissors have thick blades that are curved at a 90-degree angle. These are used commonly to separate vagina and uterus during the final steps of hysterectomy. Suture-cutting scissors have blunt, flat blades and should be reserved for this function. Use of tissue scissors for suture cutting often can dull their blades and should be avoided.

Tissue Clamps

Retraction is a fundamental requirement during most gynecologic surgery. As a result, variety of shapes, sizes, and strengths of clamps have been created to manipulate the different tissues encountered. For example, the smooth, cupped jaws of a Babcock clamp are ideal for gentle elevation of fallopian tubes, whereas the serrated teeth of the Allis and Allis-Adair clamps can provide a fine, firm grip on covering epithelia or serosa during dissection (Fig. 40-24 and 40-25).

Grasping clamps. **A.** Allis-Adair clamp. **B.** Pennington. *(From Hurt, 2002, with permission.)*

In addition to retraction, clamps are also used to occlude vascular and tissue pedicles during organ excision. Hemostats and Mixter right-angle clamps have small, slender jaws with fine inner transverse ridges to atraumatically grasp delicate tissue, especially vessels (Figs. 40-26 and 40-27).

Steps in vessel isolation, transection, and ligation. **A.** During vessel isolation, a clamp tip or fine scissors can be opened and closed parallel to the side of the vessel to dissect away loose surrounding tissue. **B.** The tip of the clamp is insinuated beneath the vessel, and the jaws are opened and elevated. **C.** Two clamps are placed around the vessel, and it is transected. **D.** The vessel then may be ligated with a free-tie suture placed around the clamp's tip and heel, or it may be coagulated. *(From, Wind, 1987, with permission.)*

Heavier clamps are required to grasp and manipulate stiffer tissues such as fascia or myometrium and include Kelly, Pean, Oschner, and Kocher clamps (Fig. 40-28). These clamps have finely spaced transverse grooves along their inner jaws to minimize tissue slippage. They may be straight or curved to fit tissue contours and, as with Kocher clamps, may contain a set of interlocking teeth at the tip for additional grip security. Another choice, the ring forceps, has large circular jaws with fine transverse grooves. These may be used to grasp broad, flat surfaces. Additionally, a folded gauze sponge can be placed between its jaws and used to absorb blood from the operative field or gently retract tissues.

FIGURE 40-28

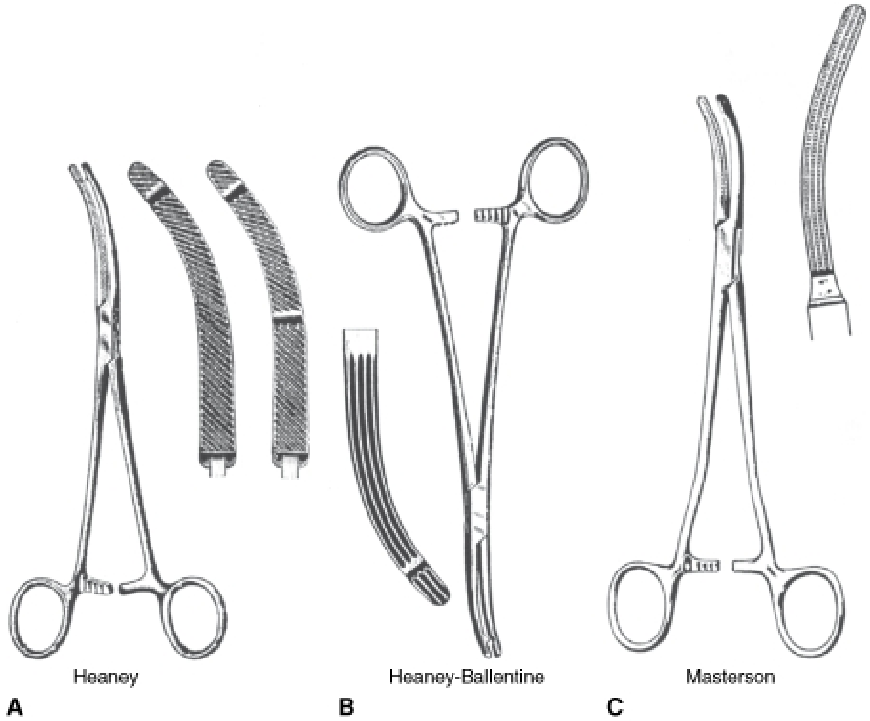
Kocher clamp. *(From Hurt, 2002, with permission.)*

Ligaments that support the uterus and vagina are fibrous and vascular. Thus, a sturdy clamp that resists tissue slippage from its jaws is required during hysterectomy. A number of clamps, including Heaney, Ballantine, Rogers, Zepplin, and Masterson clamps, among others, are effective (Fig. 40-29). The thick, durable jaws of these clamps carry deep, finely spaced grooves or serrations arranged either transversely or longitudinally for secure tissue grasping. Additionally, some contain a set of interlocking teeth at the tip or heel or both. Although this modification improves grip, it also may increase tissue trauma.

FIGURE 40-29



Heavy tissue clamps. **A.** Heaney. **B.** Heaney-Ballantine. **C.** Masterson. *(From Lipscomb, 1997, with permission.)*

Securing tissue pedicles may be accomplished using a variety of suturing techniques. A single tie alone may be placed around the pedicle, as in Figure 40-27D. In addition, a second distal transfixing suture may be placed to minimize dislodgement of the suture by vessel pulse pressures or pedicle manipulation (Fig. 40-30).

FIGURE 40-30

Suction Tips

During gynecologic surgery, bleeding, peritoneal fluids, pus, ovarian cyst contents, and irrigants may obscure the operating field. Accordingly, choice of suction tip typically is dictated by the type and amount of fluid encountered. Adson and Frazier suction tips are fine bore and are useful in shallow or confined areas and when little bleeding is noted (Fig. 40-31). Alternatively, a Yankauer suction tip offers a midrange-sized tip and is used commonly in general gynecology cases. However, if a larger volume of fluid or blood is expected, then a Poole suction tip may be desired. Its multiple pores allow continued suction even if some are obstructed with clot or tissue. Although it removes large volumes of fluid quickly, the sieved sheath may be removed, and the thinner-bore inner suction cannula can be used for finer suctioning. Larger-bore Karman suction cannulas are used for products of conception evacuation and are discussed in Section 41-17, Suction Dilatation and Curettage.

KNOTS, SUTURES, AND NEEDLES

These are foundational tools of tissue approximation, vessel ligation, and wound closure. They are crafted in a variety of strengths, shapes, and sizes to meet surgical needs. Appropriate selection can profoundly affect wound healing and patient recovery. Thus, surgeons should be familiar with their characteristics and most appropriate applications.

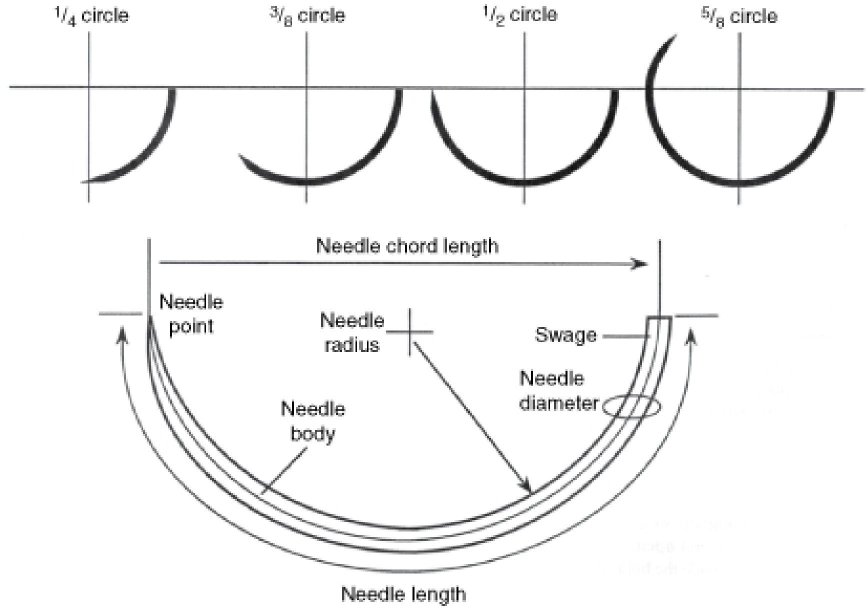
Needles

The ideal surgical needle pierces tissue with ease, with minimal tissue damage, and without bending or breaking. Tissues differ in their density and location, and thus needles are designed with variable sizes, shapes, and tips.

NEEDLE CONSTRUCTION

The anatomy of a needle is simple, and each contains a tip, body, and site of suture attachment (Fig. 40-32). For most gynecologic cases, the suture and needle used are attached as a continuous unit, which is described as *swaged.* This contrasts with needles that have eyes for suture threading. Swaged needles may be firmly secured to the suture and require cutting at the end of suturing. Alternatively, *controlled-released,* or "pop-off", swaged needles detach from the suture with a brisk tug. Controlled-release needles are used commonly when securing vascular pedicles or placing interrupted sutures. Continuous running suturing typically requires a swaged needle without the controlled-release feature.

FIGURE 40-32



Various needle configurations and characteristics of a curved surgical needle. *(Modified from Dunn, 2005, with permission.)*

In certain urogynecologic procedures, such as abdominal sacrocolpopexy, *double-armed suture* is often chosen. This suture contains identical swaged needles at each of its ends. This design enables surgeons to suture distant tissues with different ends of the suture before approximating them.

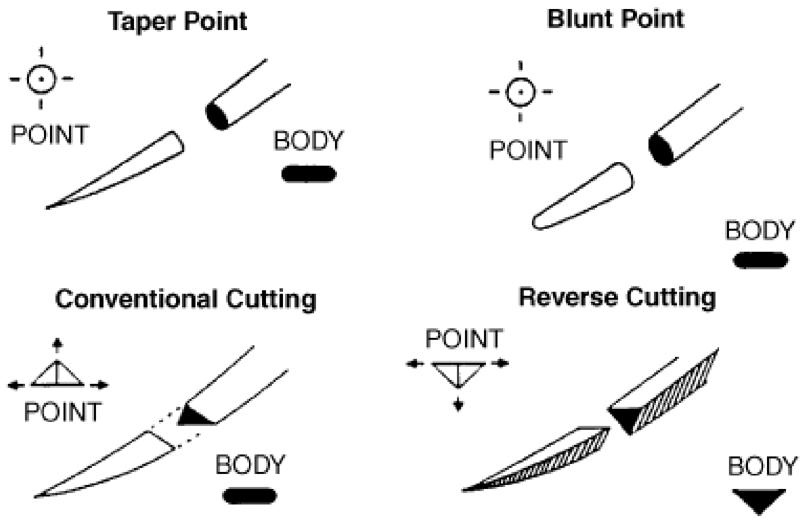
Descriptors of needle size and shape are noted in Figure 40-32. Of these, needle radius, circle configuration, and gauge more frequently influence surgical selection. For example, a needle should be large enough to pass completely through the tissue and exit far enough to allow the needle holder to be repositioned on the end of the needle at a safe distance from the tip. Repeated grasping of the needle tip leads to a dulled tip. This subsequently leads to difficult tissue penetration and greater tissue trauma.

For thicker tissues, a larger radius and gauge are warranted. For confined surgical spaces, a needle with smaller radius and greater circle configuration typically is required. Thus, for most gynecologic procedures, a three-eights or one-half circle configuration is used. For some urogynecologic operations, a five-eights circle configuration is preferred.

NEEDLE POINT

The tip should allow passage of the needle through tissue with the smallest degree of tissue damage. Those with tapered points are used for suturing thin tissues, such as peritoneum (Fig. 40-33). Alternatively, cutting needles are preferred for denser tissue such as fascia and ligaments.

FIGURE 40-33



Configurations of various needle tips and bodies. *(Modified from Dunn, 2005, with permission.)*

Cutting points have sharp edges laterally and a third sharp edge extending either toward or away from the needle's inner curve. A conventional cutting needle features the third cutting edge on the inside curve and provides shallower tissue bites. In contrast, reverse cutting needles have the third cutting edge directed away from the inner curve of the needle and are used for particularly tough tissues.

Sutures

Sutures should maximize wound healing and tissue support. Thus, surgeons should be familiar with the qualities of a particular suture for a given clinical setting (Table 40-3 and 40-4). In addition, sutures may be categorized by their biologic or synthetic derivation, their filamentous structure, and their ability to be degraded and reabsorbed.

BIOLOGIC OR SYNTHETIC SUTURES

Sutures such as catgut, silk, linen, and cotton are derived from biologic sources. As a group, biologic sutures produce the greatest

tissue reaction and have the lowest tensile strength profile. Accordingly, most suture materials currently used in gynecologic surgery are synthetic.

MONOFILAMENT OR MULTIFILAMENT SUTURE

The number of strands that comprise a given suture defines it either as *monofilament* or *multifilament.* Monofilament suture is constructed as a single strand, whereas multifilament suture contains multiple strands that are braided or twisted. Monofilament sutures have lower friction coefficients and therefore pull more easily through tissues, and as a result, create less tissue injury. As a group, they tend to incite less tissue reaction. Moreover, braid crevices are absent, and bacteria therefore are less likely to adhere (Bucknall, 1983; Sharp, 1982). However, monofilament sutures are in general less pliant for knot tying and, if knicked by instruments, are more prone to breakage.

ABSORBABLE OR NONABSORBABLE SUTURE

The rate at which tensile strength is lost differentiates suture types, and suture that has lost most of its tensile strength by 60 days following surgery is considered to be *absorbable* (Bennett, 1988). Absorbable suture is destroyed enzymatically or hydrolyzed, whereas nonabsorbable suture persists and ultimately is encapsulated.

Ideally, absorbable suture material remains throughout wound healing but no longer. Individual tissue characteristics typically dictate whether short- or long-term sutures are required for adequate wound healing. Thus, nonabsorbable suture is indicated when long-term approximation or support is required. Accordingly, nonabsorbable material plays a greater role in pelvic floor reconstruction procedures, whereas absorbable suture is used routinely in general gynecologic surgery.

REACTIVITY

All sutures, when placed within tissue, will incite inflammation. This response mirrors the total amount of suture placed and the suture's chemical composition (Edlich, 1973). In general, lower inflammatory responses are elicited by monofilament structure compared with multifilament, and synthetically derived compared with natural fiber (Lin, 2006; Sharp, 1982).

CAPILLARITY AND FLUID ABSORPTION

The ease of fluid to wick from the wet end of a suture to its dry end defines its *capillarity.* A suture's *fluid absorption ability* describes the amount of fluid it absorbs when immersed. Both properties are presumed to have an impact on the access of contaminating bacteria. Increased capillarity and fluid absorption ability greatly increase the amount of bacteria similarly absorbed (Blomstedt, 1977). In general, multifilament sutures, even those with coatings, display greater capillarity compared with synthetic monofilament sutures (Geiger, 2005).

CALIBER

The diameter of a suture reflects its size and is measured in tenths of a millimeter. A midpoint diameter size is designated as 0, and as suture diameter increases above this, arabic numbers are assigned. For example, no. 1 catgut is thicker than 0 catgut.

As suture diameter decreases from this midpoint, 0s are added. By convention, an arabic number followed by a 0 also may be used to reflect the total number of 0s. For example, 3-0 suture also may be represented as 000. Moreover, 3-0 suture is greater in diameter than 4-0 (0000) suture.

Ideally, the appropriate suture caliber is small enough to limit tissue damage during placement and minimize subsequent tissue reaction yet provide ample tensile strength to support and approximate involved tissues.

TENSILE STRENGTH

Defined as the amount of weight necessary to break a suture divided by its cross-sectional area, *tensile strength* is an important characteristic for suture selection. Ideally, the tensile strength of material chosen should approximate the strength of the tissues being sutured.

ELASTICITY, PLASTICITY, MEMORY

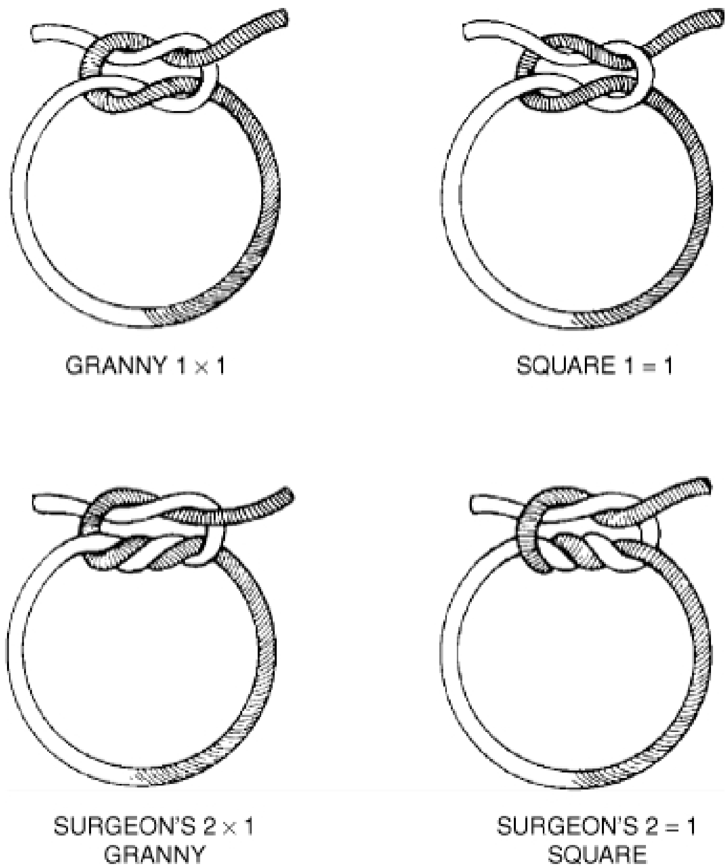
The ability of a material to return to its prior length following stretch defines its *elasticity. Plasticity,* however, describes the

tendency of material to retain its new shape once stretched. For tissues in which swelling or movement is expected postoperatively, a suture with increased elasticity is preferred because it will stretch rather than cut into approximated tissues. *Memory* defines the ability of material to return to original form following deformation. Sutures with greater memory tend to untie more easily during knot tying.

Knots

In gynecologic surgery, knots secure sutures during vessel ligation, creation of reconstructive support, and incision reapproximation. A number of knotting styles are available to the surgeon, but square knot, surgeon's knot, and slip knot are used most commonly (Fig. 40-34).

FIGURE 40-34



Source: Schorge JO, Schaffer JI, Halvorson LM, Hoffman BL, Bradshaw KD, Cunningham FG: *Williams Gynecology*: http://www.accessmedicine.com

Surgical knots. *(From Cunningham, 2002, with permission.)*

The number and type of knots required to secure various suture material vary, and qualities such as elasticity, plasticity, and memory often direct these recommendations. In general, multifilament sutures are easier to handle and display less memory. For these, square knots are appropriate. Synthetic monofilament suture materials or multifilament sutures with coatings, however, have increased memory and may hold a knot poorly. Thus, a surgeon's knot typically is recommended. In addition, each additional throw of a knot up to a certain point adds security. After this threshold, additional throws only serve to increase suture breakage and to act as a nidus for infection.

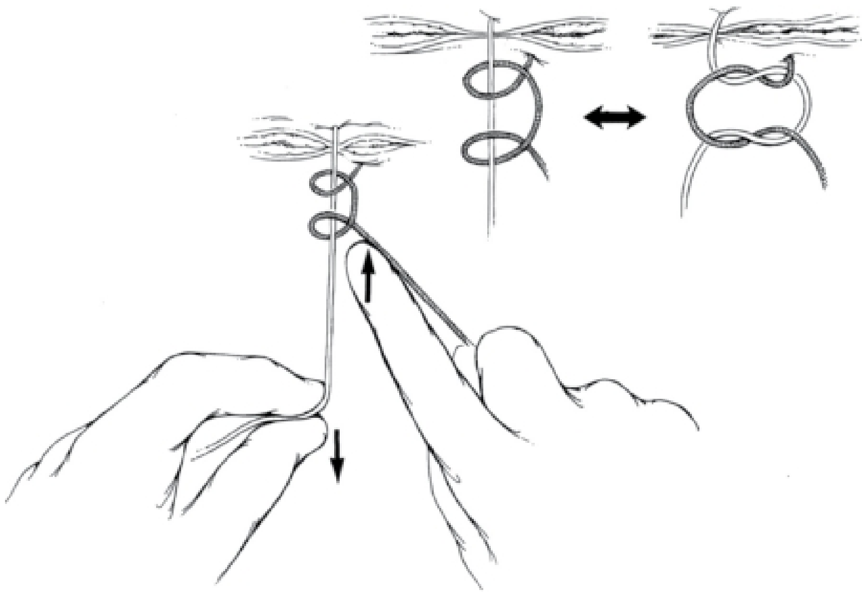
In characterizing knots, each loop is given a numerical description. Loops with a single throw are noted as 1, whereas a loop with

two throws, as in a surgeon's knot, is assigned the number 2. If successive loops are identical, as with a granny knot, then a multiplication sign is placed between loop numbers. If loops mirror one another, as in the square knot, then an equal sign is used. Thus a square knot is described as 1 = 1; granny knot, 1 × 1; and square surgeon's knot, 2 = 1.

Knots are typically the weakest part of any suture, and the force necessary to break a knotted suture is less than that to break an individual suture strand. In addition, knot strength is affected by the speed at which force is applied to the knot. Abrupt tightening of knots may break sutures more easily than slowly securing them.

Of those used by gynecologists, square knots are considered the strongest, followed by surgeon's and granny knots. Slip knots are the weakest but are used often of necessity by gynecologists. Deep, narrow operating spaces may limit the hand crossing needed for square knotting (Fig. 40-35). If slip knots are placed initially to approximate tissue, they should be converted to square knots or reinforced with a square knot once the pedicle or vessel is secured.

FIGURE 40-35



Source: Schorge JO, Schaffer JI, Halvorson LM, Hoffman BL, Bradshaw KD, Cunningham FG: *Williams Gynecology*: http://www.accessmedicine.com

A slip knot can be converted to a square knot by applying tension primarily to one suture end. *(Modified from Edlich, 2005, with permission.)*

ELECTROSURGERY

Electrosurgery is one of the most commonly used surgical tools and enables surgeons to coagulate vessels and incise tissues rapidly. Familiarity with its basic principles can increase its effective use and minimize tissue injury.

Semantically, *electrosurgery* differs from *electrocautery,* although the terms are often incorrectly interchanged. Electrocautery is not used commonly in gynecologic surgery, and with it, electric current passes through a metal object, such as a wire loop, with internal resistance. Passage of the current through the resistance heats the loop, which then may be used surgically. The flow of current is limited to the metal being heated, and no current enters surgical tissues.

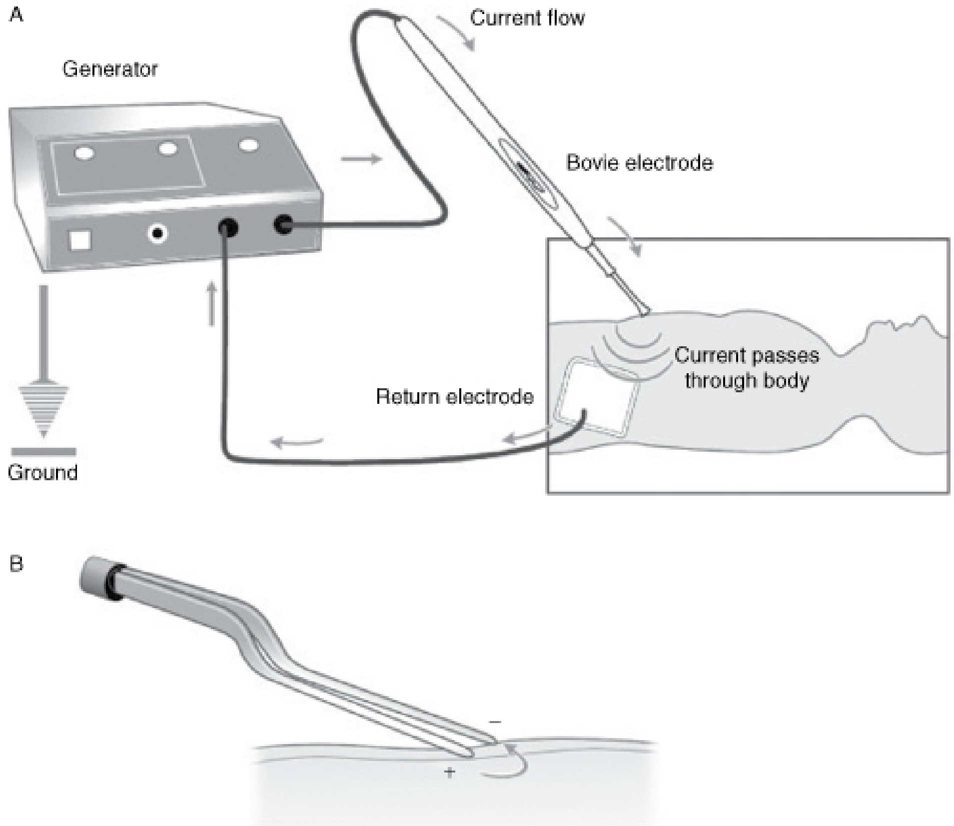
In contrast, electrosurgery directs the flow of current to the tissues themselves and produces localized tissue heating and destruction. As a result, electric current must pass through tissues to produce the desired effect (Amaral, 2005).

Monopolar Electrosurgery

Electric current is the flow of electrons through a circuit (Fig. 40-36). Voltage is the force that drives those charges around the circuit. Impedance is the combination of resistance, inductance, and capacitance that alternating current meets along the way

(Morris, 2006). In surgery, the electrosurgical circuit consists of four primary parts: the electrosurgical generator, active electrode, patient, and return electrode, which in clinical use is the grounding pad. Current flows: (1) from the generator, which is the source of voltage, (2) through the electrosurgical tip to the patient, the source of impedance, and then (3) onto the grounding pad, where it is dispersed. Current leaves the pad to return to the generator, and the circuit is completed (Deatrick, 2006).

FIGURE 40-36



Circuits in electrosurgery. **A.** Monopolar electrosurgical circuit. **B.** Bipolar electrosurgical circuit. *(From Deatrick, 2006, with permission.)*

In electrosurgery, tissue impedance converts electric current into thermal energy that causes tissue temperatures to rise. It is these thermal increases that create electrosurgery's tissue effects.

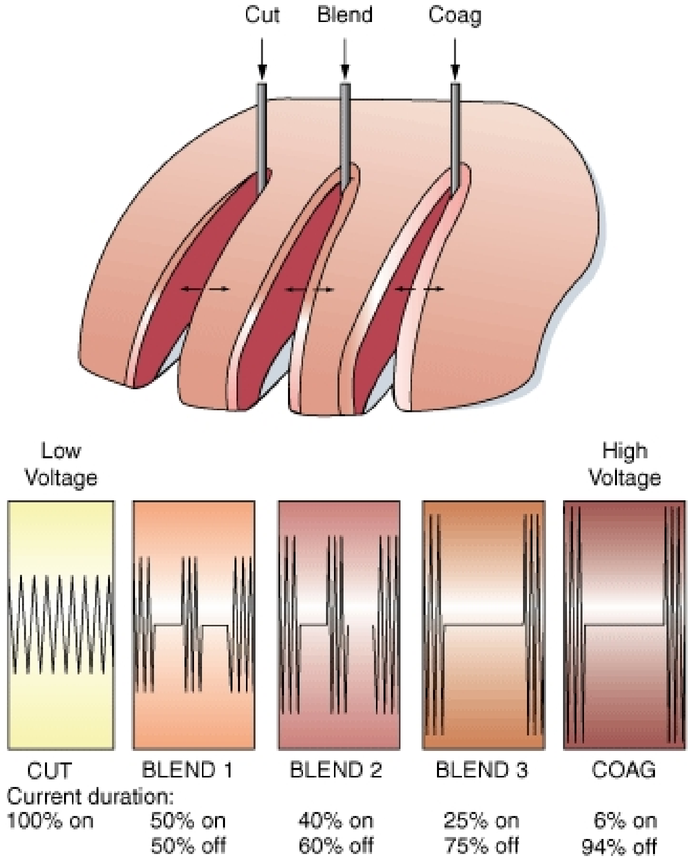
The current from a wall outlet that powers electrosurgical generators has a frequency of 60 Hz (in the United States) or 50 Hz (in other parts of the world). Extreme neuromuscular stimulation can result from this lower frequency, as with electrocution. However, at frequencies above 100 Hz, excitable membranes are not depolarized, and thus nerve and muscles responses are bypassed. For safe use during electrosurgery, modern surgical generators increase frequencies to greater than 200 Hz (Valleylab, 2006).

Surgical Effects

Differing tissue effects are created by altering the manner in which current is produced and delivered. First, altering the current wave pattern can affect tissue temperatures. For example, the high-frequency continuous sinusoidal waveform produced with cutting current creates higher tissue temperatures than that with coagulation current (Fig. 40-37). Second, the extent to which current is spread over an area, also termed *current density,* alters the rate of heat generation. Thus, if current is concentrated onto a small area such as a needle-tip electrode, greater tissue temperatures are generated than if delivered over a wider area such as an electrosurgical blade. In addition to current density, voltage can alter tissue effects. As seen in Figure 40-37, as voltage

increases, the degree of thermal tissue damage similarly increases. And finally, the qualities and impedance of the tissues themselves affect energy transfer and heat dissipation. For example, water has low electrical impedance and liberates little heat, whereas skin with its greater impedance generates significantly higher tissue temperatures (Amaral, 2005).

FIGURE 40-37



Source: Schorge JO, Schaffer JI, Halvorson LM, Hoffman BL, Bradshaw KD, Cunningham FG: *Williams Gynecology*: http://www.accessmedicine.com

Tissue effects vary with cutting, blended, and coagulation currents. There is more lateral thermal damage with a pure coagulation current compared with a pure cutting or blended current. The duration of applied energy varies between current types.

CUTTING CURRENT

With electrosurgical cutting, a continuous sine wave of current is produced. The flow of high-frequency current typically is concentrated through an electrosurgical needle or blade and meets tissue impedance. Sparks are created between the tissue and electrode, intense heat is produced, cellular water vaporizes, and cells in the immediate area burst. Tissues are cut cleanly, and there is minimal coagulum production. As a result, few vessels are sealed, and minimal hemostasis accompanies electrosurgical cutting.

COAGULATION CURRENT

In contrast with cutting current, coagulation current does not produce a constant waveform. Less heat is produced than with cutting current. However, tissue temperature still rises sufficiently to denature protein and disrupt normal cellular architecture. Cells are not vaporized instantly, and cellular debris remains associated with wound edges. This coagulum seals smaller blood vessels and controls local bleeding (Singh, 2006).

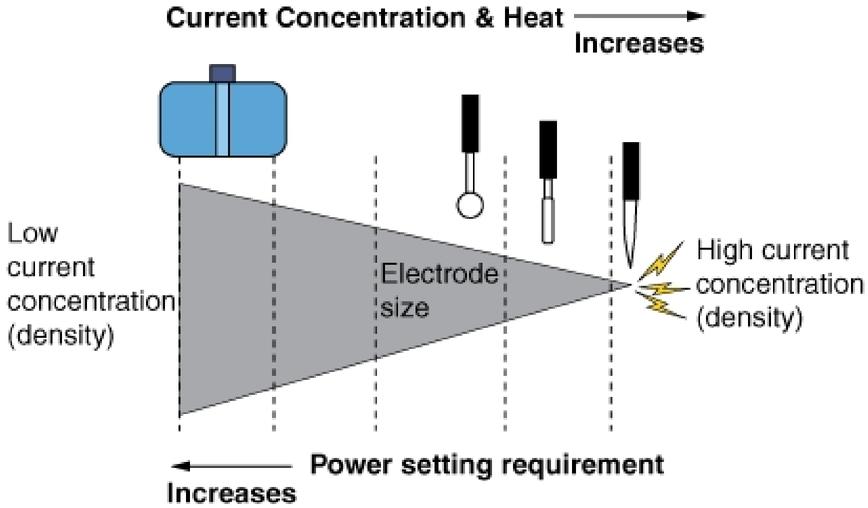
BLENDED CURRENT

Variations in the percentage of time that current is flowing can create electrosurgical effects that contain both cutting and coagulating features. Such *blended currents* are used commonly in gynecologic surgery. In most cases, selection of specific percentages of cutting and coagulation current is affected by surgeon preference and type of tissues encountered. Thinner vascular tissue may be best suited for a blend with less active current time, whereas denser avascular tissues may require a greater percentage of active current.

Patient Grounding

As discussed earlier, current is concentrated at the electrode tip and enters the patient at a small site. Current follows the path of least resistance and exits the body through a grounding pad that is designed to have a large surface area, high conductivity, and low resistance (Fig. 40-38). Dissipation across this large surface area allows current to leave the body without generating significant tissue temperatures at the exit site.

FIGURE 40-38



Current concentration and its effects. Thermal energy and risk for tissue injury diminish as current density decreases and electrode area increases.

However, patient burns may result if current is again concentrated through a return electrode. Clinically, this may occur if a grounding pad is partially dislodged. In this setting, the surface area is decreased, and exiting current concentration and tissue temperatures at the exit site rise. In addition, patient jewelry, metal candy cane stirrups, or other surfaces with high conductivity and low resistance may serve as a return electrode. In such cases, patient may be burned by concentrated current exiting through these small contact sites.

Ideally, grounding pads should be firmly adhered to a relatively flat body surface that is near the operative field. Thus, in most gynecology procedure, grounding pads are placed along the lateral upper thigh.

Bipolar Electrosurgery

This form of electrosurgery differs from monopolar electrosurgery in that the tip of a bipolar device contains both an active and a return electrode (see Fig. 40-36B). For this reason, a distant grounding return pad is not required. Coagulation current is concentrated on tissues grasped between the electrodes, and tissue must remain between them. If tissue slips from between the tips, then active and return electrodes contact and create a short circuit. Coagulation will not occur (Michelassi, 1997). Bipolar electrosurgery uses only coagulation current and lacks cutting capability. However, it is useful for vessels coagulation and also is used during laparoscopic sterilization to coagulate fallopian tubes (see Section 41-29, Laparoscopic Sterilization).

Argon Beam Coagulation

This tool represents a modification of conventional electrosurgical coagulation. With argon beam coagulation (ABC) radiofrequency energy is transferred to tissues through a jet of inert argon gas to create noncontact monopolar electrothermal coagulation. Additionally, the gas jet clears blood and tissue dÃ©bris during coagulation. Advantages of ABC include the ability to coagulate broad surface areas and larger vessels (Beckley, 2004). In gynecologic surgery, ABC is used most commonly during ovarian staging cases in which extensive debulking may be required.

Coexisting Electrical Devices

Patients with pacemakers, internal cardioverter-defibrillators (ICDs), or other electrical implants require special precautions. Stray electrosurgical current may be interpreted as an intracardiac signal by an implanted device and lead to pacing changes. In addition, myocardial electrical burns may result from conduction of current through the pacing electrode rather than through the grounding pad (Pinski, 2002).

Accordingly, for patients with these devices, preventative recommendations include pre- and postoperative cardiology consultation, use of minimal monopolar electrosurgical current settings or substitution with bipolar electrosurgery or harmonic scalpel, continuous cardiac monitoring, contingency plans for arrhythmias, and an adequate distance between the active and return electrodes (El-Gamal, 2001).

ULTRASONIC ENERGY

Sound waves are mechanical waves that transport energy through a medium. Those above audible range are described as *ultrasound* or *ultrasonic.* In medicine, ultrasound waves that are applied at low levels such as those used in diagnostic sonography are harmless. However, if higher power levels are used, then mechanical energy of sufficient strength is transferred to the impacted tissues, and cutting, coagulation, or tissue cavitation is produced.

Ultrasonic Scalpel

The tip of an ultrasonic scalpel, also known as a *harmonic scalpel,* vibrates at high frequency, allowing the surgical device to be used effectively for both cutting and coagulating during laparotomy or laparoscopy (Gyr, 2001; Wang, 2000). The vibrating tip transfers mechanical energy to tissues. Mechanical energy breaks hydrogen bonds and generates heat within tissues to denature protein and form a sticky coagulum that produces hemostasis (Amaral, 1993)

A balance between cutting and coagulation is created by controlling three factors: power levels, tissue tension, and blade sharpness. Higher power level, greater tissue tension, and a sharp blade will lead to cutting, whereas lower power, decreased tissue tension, and a blunt blade will create slower cutting and greater hemostasis (Sinha, 2003).

Used most commonly in laparoscopic surgery, the ultrasonic scalpel serves as an alternative to suture ligation, electrosurgical coagulation, laser, and stapling or clipping devices. However, only a few studies have been published comparing the clinical effectiveness of this method with other methods of hemostasis (Kauko, 1998).

Cavitational Ultrasonic Surgical Aspiration

An ultrasonic surgical aspirator hand-piece contains three main components: a high-frequency vibrator, which transfers the ultrasonic energy to tissues; irrigation tubing, which directs cooling saline to the tip; and a suction system, which draws tissue up to the tip for contact with the vibrator and which also clears away tissue fragments and irrigant. Ultrasound energy can be used to raise tissue temperatures dramatically and thereby disrupt tissue architecture by a process termed *cavitation.* With cavitation, a rapidly oscillating cavitational ultrasonic surgical aspiration (CUSA) tip produces mechanical waves that create heat and vapor pockets around cells in tissues with high water content such as fat, muscle, and carcinoma. Collapse of these pockets leads to disruption of cell architecture (Jallo, 2001). Affected tissues are removed subsequently by suction aspiration. However, tissues containing less water and higher contents of collagen and elastic fibers, such as blood vessels, nerves, ureters, and serosa, are more resistant to damage (van Dam, 1996).

In gynecology, CUSA has a limited surgical role and has been used in the treatment of vulvar intraepithelial neoplasia, bulky

condyloma accuminata, and cytoreductive ovarian cancer surgery (Aletti, 2006; Deppe, 1988; Robinson, 2000; van Dam, 1996).

MANAGEMENT OF HEMORRHAGE

Ideally, problematic bleeding is avoided during surgery by optimizing preoperative preparations, ensuring adequate operative exposure, and using proper surgical technique. However, if hemorrhage does occur, surgeons should be familiar with its appropriate management.

Optimizing Preoperative Preparations

Although the risk of hemorrhage accompanies most gynecologic procedures, certain factors are associated with higher rates of bleeding and should be assessed prior to surgery. Specifically, obesity, the presence of a large pelvic mass, adhesions such as those from endometriosis or pelvic inflammatory disease, cancer or prior radiation, and coagulation dysfunction all have been linked with an increased risk of hemorrhage. For those identified to be at risk, intraoperative red cell salvage or preoperative autologous blood donation may be considered.

RED BLOOD CELL SALVAGE

Red blood cell (RBC) salvage machines (Autolog, Medtronic, Minneapolis, MN; CATS, Fresenius, Redmond, WA; Cell Saver, Haemonetics Corp., Braintree, MA) collect, filter, and centrifuge blood lost during surgery and may be helpful in patients in whom increased intraoperative hemorrhage is anticipated. RBCs are heavier and are separated from plasma and smaller blood components during centrifugation and then reinfused into the patient. Anticoagulants such as heparin or citrate are added to prevent clotting (Karger, 2005).

Salvage efficiencies approximate 60 percent with good technique. However, vacuum levels, suction tip size, and thoroughness of salvaging efforts can affect this value. For example, turbulence destroys RBCs. Thus, suction tips with greater diameters and lower suction force can minimize hemolysis (Waters, 2005). Additionally, laparotomy sponges can be rinsed in sterile saline to maximize RBC removal. The RBC-containing saline then is suctioned into the salvage device for processing.

Filtering systems in these devices have limitations. Accordingly, RBC salvage is not appropriate for contaminated cases or those in which malignancy, hemostatic agents, or amnionic fluid may be present (Waters, 2004).

PREOPERATIVE AUTOLOGOUS DONATION

To avoid potential transfusion reaction or blood-borne infection, a patient may elect to donate her own blood for personal use approximately once a week for 3 to 5 weeks preceding surgery. Patient hemoglobin levels should be greater than 11.0 g/dL before each donation. Moreover, units should not be collected within 72 hours before surgery. This allows intravascular volume to be repleted by the patient and units to be processed by the blood bank (Goodnough, 2005). Disadvantageously, this process has been associated with preoperative anemia secondary to donation, more liberal transfusion, transfusion reaction following clerical error, volume overload, and bacterial contamination of blood products during processing (Henry, 2002; Kanter, 1996, 1999).

Improved blood banking safety has accompanied a decline in PAD (Brecher, 2002). Moreover, for most gynecologic cases, the risk of transfusion is low. For these reasons, autologous donation typically is reserved for selected instances in which the risk of transfusion is significant, such as radical hysterectomy or surgery for patients with coagulopathies. Additionally, patients with rare blood phenotypes in whom acquisition of compatible blood may be difficult may benefit from PAD.

Proper Surgical Method

In many instances, proper surgical technique may minimize vascular injury and hemorrhage. Thus, prior to ligation, vessels should have excess connective tissue removed with fine scissors in a process called *skeletonizing.* Additionally, tissue clamps selected for grasping a vascular pedicle should be large enough to contain the entire pedicle in the distal portion of the clamp. Large pedicles that force excess tissue toward the clamp heel carry greater risk of tissue slipping from the heel and bleeding. Once secure, sutures placed on vascular pedicles should not be used for traction because the risk of avulsing the suture or vessel increases.

Steps of Hemorrhage Management

A methodical approach to intraoperative hemorrhage is critical to minimize patient injury. If an isolated vessel is clearly identified, then grasping it with a hemostat, vascular clamp, or fine forceps may allow ligation, electrosurgical coagulation, or vascular clip application.

In contrast, venous bleeding in the pelvis is typically from a venous plexus and rarely stems from a single vessel. Pelvic venous plexuses contain thin-walled veins. Accordingly, indiscriminate clamping, suturing, clipping, and electrosurgical coagulation may cause further laceration and bleeding. However, if other vulnerable structures have been retracted and protected, a few shallow stitches that incorporate such a bleeding area may be placed using fine absorbable suture.

If these initial efforts are unsuccessful and significant hemorrhage continues, the bleeding site is compressed with fingertip or sponge stick. Anesthesia staff should be informed of events to allow for additional monitoring. Resuscitative efforts with crystalloid or blood products are individualized depending on the degree of hemorrhage and other patient factors (Fluid Resuscitation and Blood Transfusion).

Adequate exposure of the bleeding site typically is needed to gain control of bleeding. The operative field should be assessed and increased as needed by extending a vertical incision cephalad, converting a Pfannenstiel to a Maylard incision, adding retractors, or converting a vaginal or laparoscopic approach to laparotomy. The site of bleeding should be evacuated of blood, and a second suctioning system may be indicated. Additional dissection of avascular planes around the bleeding site may improve isolation and ligation of a lacerated vessel. Furthermore, nearby vulnerable structures such as the bladder, ureter, or other vessels should be identified and protected.

After these steps, the surgeon may remove the tamponading finger to assess the location, amount, and character of bleeding and to formulate the most appropriate technique for control.

VESSEL LIGATION

Suture Ligature

Surgical knots have been used since the beginning of surgery to prevent blood loss during operative dissection and resection. Advantages to suture ligation include low cost and effectiveness over a broad range of vessel diameters. However, knot tying in general is time-consuming, limited in narrow spaces, and less commonly, associated with ligature slippage or breakage.

Small vessels may be ligated by a free-tie suture placed around the heel and tip of a vascular clamp and then secured with knots (see Fig. 40-27). Alternatively, surgeons often prefer to secure larger vascular pedicles with two separate sutures. The first ligature is a free tie placed around the toe and heel of a vascular clamp and tied. The second ligature is distal to the first and typically incorporates a bite through the tissue pedicle (see Fig. 40-30). Such *transfixion* of the ligature to the pedicle decreases the risk of it slipping off the pedicle's end. Importantly, placement of this second ligature distal to the first avoids hematoma formation if a vessel is pierced during transfixion.

Clips

Titanium clips seal vessels by direct compression. They are used more commonly during gynecologic oncology cases and offer the advantage of speed. However, clips are expensive, require surgical dissection of the vessel prior to application, and may dislodge from a vessel. Their use in routine gynecology is limited by these factors and surgeon preference.

Electrosurgical Seal

Electrical and ultrasound energy also may be used to seal vessels. Ultrasonic coagulating shears LaparoSonic Coagulation Shears, Ethicon, Pittscataway, NJ) and electrosurgical bipolar vessel sealing clamps (Ligasure, Valleylab, Boulder, CO) transfer energy that denatures vascular collagen and elastin and seal vessels up to 7 mm in diameter (Heniford, 2001). Thermal spread for both devices is comparable and averages 2.5 mm (Harold, 2003). These tools are particularly useful for laparoscopic surgeries, in which knot tying is time-consuming (Ding, 2005; Hagen, 2005; Hefni, 2005; Tamussino, 2005).

LOCAL HEMOSTATIC AGENTS

These topical products may be placed on bleeding sites where ligature or electrosurgical or ultrasonic vessel coagulation is not possible or has been ineffective. They are most effective in controlling low-pressure bleeding, such as from veins, capillaries, and

small arteries. Commercially available materials include those listed in Table 40-5. Some liquid hemostats deliver topical thrombin or thrombin and fibrinogen and thereby induce clot formation. Others transmit direct pressure against wound surfaces, entrap platelets, promote platelet aggregation, and serve as a scaffold on which clot can organize.

Table 40-5 Topical Hemostatic Agents

Type of Agent	Brand Name	Material
Oxidized, regenerated cellulose	Surgicel	Flat, fabric-like
Bovine collagen	Avitene, Instat	Powder, compressed sheet, or thin, flat sponge
Bovine thrombin	Thrombin-JMI	Liquid spray
Porcine gelatin	Surgifoam; Gelfoam	Putty or thin, flat sponge
Bovine thrombin and gelatin	FloSeal Matrix	Liquid
Human thrombin + fibrinogen	Crosseal; Tisseel	Needle tip or spray applicator

Although effective, these agents do have disadvantages. They should not be introduced intravascularly or used with cell salvage machines. Packing agents tightly into bony foramina should be avoided because these agents may swell, causing neurologic dysfunction or pressure necrosis. Moreover, they should not be placed within skin edges because they may retard edge reapproximation. Those composed of gelatin, collagen, or cellulose can serve as an infection nidus and thus, may not be appropriate in grossly infected tissue (C.R. Bard, 2007; Baxter, 2006; Pfizer, 2006).

Little data support the use of one agent over another. Selection typically is dictated by surgeon preference and operating room availability of an agent.

Specific Sites of Bleeding

Bleeding can develop during any type of gynecologic surgery. However, there are vascular complications that characteristically may complicate specific procedures, and surgeons may benefit from a familiarity with their management.

INFUNDIBULOPELVIC LIGAMENT

During or after ligation of this vascular pedicle, a lacerated ovarian vessel may retract into the retroperitoneum to create a hematoma. In most cases, isolation of the bleeding vessel is required to halt hematoma expansion.

Initially, the pelvic sidewall peritoneum lateral to the hematoma and the ureter is opened, and the incision is extended cephalad with fine scissors to the upper pole of the hematoma. Here, ovarian vessels are identified, and a closed Mixter right-angle clamp is placed under them. A free-tie pass then is threaded beneath and used to ligate these vessels. The hematoma then is evacuated to minimize infection risk.

In rare cases in which vascular or ureteral anatomy is unclear, an ovarian artery may require ligation as proximal as its aortic origin below the renal arteries (see Fig. 38-15) (Masterson, 1995).

PRESACRAL VENOUS PLEXUS

Sacrocolpopexy requires entry into the retroperitoneum and the presacral space (see Fig. 38-24). During entry, the presacral venous plexus can be injured during dissection or suturing. Vessels may retract into the vertebral bone, and problematic bleeding may result. Initially, injury to the plexus is managed with constant pressure over several minutes. As pressure is removed, an isolated vessel may be identified and sutured with fine absorbable suture. Extensive suturing, however, is discouraged because this can lead to additional vessel laceration and bleeding. Alternative methods of control have included the use of bone wax, insertion of a sterile thumbtack through the vessel and into the vertebral bone, and placement of hemostatic agents such as Floseal Hemostatic Matrix (Baxter, Deerfield, IL). In rare refractory cases, patient packing as described below may be required.

SPACE OF RETZIUS

This space is commonly entered during urogynecologic procedures and contains important vascular structures such as the venous plexus of Santorini, the obturator vessels, and the aberrant obturator vessel (see Fig. 38-25). (Baggish, 2001). Bleeding complications may develop, and approximately 2 percent of tension-free vaginal tape procedures are complicated by bleeding in this space (Kolle, 2005; Kuuva, 2002). In most instances, bleeding is controlled with pressure or suturing.

MAJOR PELVIC VESSELS

Fragile, high-volume veins within the pelvic sidewall include the internal, external, and common iliac veins and the inferior vena cava. These may be lacerated during tumor removal, endometriosis excision, or laparoscopic trocar placement. At times during lymphadenectomy, small veins that enter the anterior surface of the common iliac vein or the inferior vena cava may be avulsed.

In those comfortable with such vascular repair, a figure-of-eight or continuous running stitch may be placed with a 5-0 permanent monofilament suture (Gostout, 2002). Although gynecologic surgeons may attempt to repair these injuries, excessive delay in obtaining vascular surgery assistance often leads to greater blood loss (Oderich, 2004). Therefore, in many instances, pressure is applied, and a vascular surgeon is consulted for repair.

As discussed below, although internal iliac artery ligation does not lead to ischemia of central pelvic organs, injury to the external or common iliac arteries requires repair to maintain blood supply to the lower extremity. Consultation with a vascular surgeon may be indicated depending on the degree of laceration and surgeon skill. Such arterial tears may be closed with a continuous suture line using monofilament synthetic 5-0 suture (Tomacruz, 2001).

PARAMETRIAL AND PARAVAGINAL VESSELS

During obstetric and gynecologic surgery, laceration to vessels supplying the uterus and vagina, especially venous plexuses, may result in bleeding that cannot be easily identified and controlled following application of direct pressure, suturing, or a clip. In these extreme situations, ligation of the internal iliac artery, which is a main source of blood supply to the pelvis, may decrease pooling of blood and afford a better opportunity to find a bleeding source. Alternatively, if resources are available, pelvic artery embolization has been shown to be effective in controlling pelvic hemorrhage. Despite these techniques, in rare persistent situations, pelvic packing and termination of surgery may be indicated.

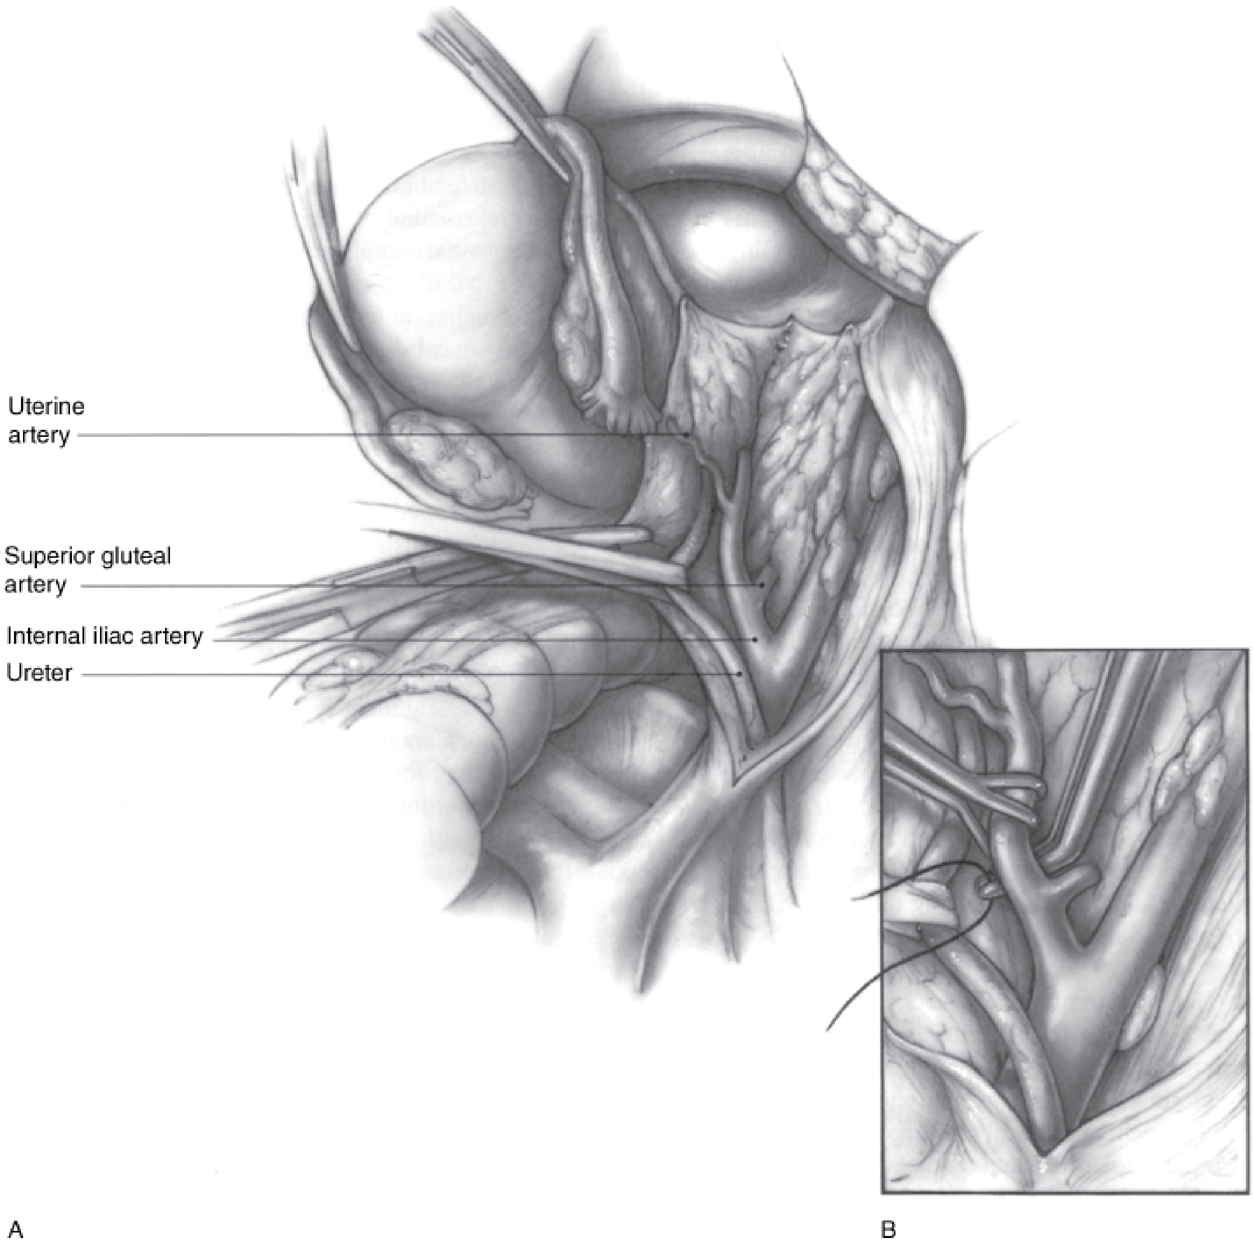
Internal Iliac (Hypogastric) Artery Ligation

The internal iliac artery, also known as the *hypogastric artery,* contains anterior and posterior divisions. Its anterior division supplies blood to central pelvic viscera (see Fig. 38-22). The female pelvis has extensive collateral circulation, and the internal iliac artery shares arterial anastomoses with branches of the aorta, external iliac artery, and femoral artery. For this reason, ligation of the internal iliac's anterior division can be performed without compromise to pelvic organ viability. Several studies have described normal postligation fertility in these women, and an investigation evaluating flow with color Doppler sonography showed recanalization of ligated arteries within an average of 5 months (Demirci, 2005; Khelifi, 2000; Nizard, 2003). Occlusion of the internal iliac artery decreases mean blood flow in branches distal to ligation by 48 percent, which in many cases slows hemorrhage sufficiently to allow identification of specific bleeding sites (Burchell, 1968).

To perform ligation, the round ligament is divided, and the pelvic sidewall peritoneum lateral to the infundibulopelvic ligament is incised cephalad. Identification of the internal iliac artery is essential because ligation of the common or external iliac arteries will have vascular consequences to the lower extremity.

Once the vessel is located, a Mixter right-angle clamp is placed under the vessel, and two free ties of no. 1 or 0 absorbable suture are passed beneath and then secured (Fig. 40-39). The artery is ligated but not transected (Gilstrap, 2000). Care is required in passing instruments beneath the artery because the thin-walled internal iliac vein is easily lacerated.

FIGURE 40-39



Internal iliac artery ligation. **A.** After opening the retroperitoneal space, the ureter is identified and retracted medially. **B.** The internal iliac artery is identified and gently elevated with a Babcock clamp. A Mixter right-angle clamp is placed beneath the artery to receive a free tie for ligation. *(From Gilstrap, 2002, with permission.)*

Pelvic Artery Embolization

As described in Chapter 9, Uterine Artery Embolization, embolization similar to that used to treat symptomatic leiomyomas can be used to occlude either the internal iliac artery or the uterine artery. This technique has been described in the management of hemorrhage in both gynecologic and obstetric cases (Kim, 2004; Pearl, 1992; Shim, 2006).

Pelvic Packing

In patients with persistent heavy bleeding despite attempts at control, pelvic packing with gauze and termination of the operation may be warranted. Rolls of gauze are packed against the bleeding site to provide constant local pressure. Typically, 24 to 48 hours later, if the patient is stable and bleeding appears to have stopped clinically, packing may be removed. Some surgeons recommend leaving one end of the gauze outside the wound. After administration of general anesthesia, packing is pulled slowly through a small opening left in the incision. Alternatively, entire gauze rolls may be packed into the abdomen and removed during a second laparotomy (Newton, 1988).

FLUID RESUSCITATION AND BLOOD TRANSFUSION

With acute hemorrhage, priorities include control of additional losses and replacement of sufficient intravascular volume for tissue perfusion and oxygenation. In hypoperfused areas, progressive failure of oxidative metabolism with lactate production leads to worsening systemic metabolic acidosis and eventual organ damage (Manning, 2004). To avoid these effects, resuscitation should begin with an assessment of the patient's clinical status, calculation of total blood volume, and estimation of blood loss.

Clinical Assessment

Total blood volume for an adult approximates 70 mL/kg, and thus a 50-kg woman's calculated blood volume is 3,500 mL. Of this volume, 15 percent can be lost by most patients with no changes in arterial pressure or heart rate. A 15-percent blood loss can be roughly calculated by multiplication of a patient's weight in kilograms by 10. Thus, for a 50-kg woman, a 15-percent loss approximates 500 mL.

With losses of 15 to 30 percent (500 to 1,000 mL for a 50-kg woman), tachycardia and narrowing of the pulse pressure are seen (Table 40-6). Peripheral vasoconstriction leads to pale, cool extremities and poor capillary refill. In unasthetized patients, there may be mild confusion or lethargy. In most women with normal preoperative hemoglobin levels, this amount of blood loss requires fluid volume replacement, but RBC transfusion typically is not required. Greater losses, however, lead to worsening perfusion, hypotension, and tachycardia. In these cases, blood transfusion in combination with fluid resuscitation typically is indicated (Murphy, 2001).

Table 40-6 Clinical Findings Associated with Increasing Severity of Hemorrhage

Hemorrhage Class	**Class I**	**Class II**	**Class III**	**Class IV**
Blood loss				
Percentage	<15	15â€“30	30â€“40	>40
Volume (mL)	750	800â€“1,500	1,500â€“2,000	>2,000
Blood pressure				
Systolic	Unchanged	Normal	Reduced	Very low
Diastolic	Unchanged	Raised	Reduced	Very low, unrecordable
Pulse (beats/min)	Slight tachycardia	100â€“120	120 (thready)	>120 (very thready)
Capillary refill	Normal	Slow (>2 s)	Slow (>2 s)	Undetectable
Respiratory rate	Normal	Normal	Tachypnea (>20/min)	Tachypnea (>20/min)
Urinary flow				
rate (mL/h)	>30	20â€“30	10â€“20	0â€“10

Extremities	Normal color	Pale	Pale	Pale and cold
Complexion	Normal	Pale	Pale	Ashen
Mental state	Alert	Anxious or aggressive	Anxious, aggressive, or drowsy	Drowsy, confused, or unconscious

From Baskett, 1990, with permission.

During surgery, blood collects in suction canisters and laparotomy sponges. Although calculations from these sources provide surgeons with an approximation, blood loss estimates typically are low, and inaccuracy increases as the length and extent of a procedure increases (Bose, 2006; Santoso, 2001). Additionally, a hematocrit may be measured to assess hemorrhage. However, hematocrit values typically lag true losses, and values may reflect only the degree of hemorrhage. For example, following a blood loss of 1,000 mL, hematocrit levels typically fall only 3 volumes percent in the first hour but usually reflect an 8 volume percent drop at 72 hours (Schwartz, 2006).

Fluid Resuscitation

If hypovolemia is identified, fluid resuscitation should begin with crystalloid solutions. If hypotension and tachycardia are present, rapid replacement is warranted, and 1 or 2 liters, as indicated, may be infused over several minutes. Normal saline and lactated Ringer solutions are the two crystalloids used commonly. For moderate hemorrhage, both perform equally well for fluid replacement (Healey, 1998).

Although crystalloids have an immediate effect to expand intravascular volume, a portion will extravasate into extracellular tissues. Thus, in the setting of hemorrhage, crystalloid volume should be administered in a 3:1 ratio of blood lost (Moore, 2004). Clinically, urine output of 30 mL or more per hour, heart rate less than 100 beats per minute, and systolic blood pressure greater than 90 mm Hg may be used as general indicators of volume improvement. If rapid crystalloid infusion fails to correct hypotension or tachycardia, then RBC transfusion usually is warranted.

In addition to crystalloid solutions, colloids also may be used for volume expansion. These fluids have higher molecular weights than crystalloids. As a result, a greater portion remains intravascularly and is not lost to extracellular extravasation. Despite this perceived advantage, studies comparing survival rates if crystalloids or colloids are administered find no superiority with colloids but greater expense (Roberts, 2004).

RBC Replacement

CLINICAL ASSESSMENT

The decision to administer RBCs is complex and must balance the risks of transfusion with needs for adequate tissue oxygenation. These needs will vary depending on the clinical setting, and an assessment should include hemoglobin level, vital signs, patient age, risks for further blood loss, and underlying medical conditions, especially cardiac disease. Accordingly, no specific hemoglobin threshold dictates when RBCs should be administered. However, consensus guidelines suggest that transfusion to a hemoglobin level above 10 g/dL is rarely indicated (Hill, 2002). If hemoglobin levels reach 6 g/dL, transfusion almost always is required (Madjdpour, 2006). Hemoglobin levels between 6 and 10 g/dL are more problematic, and patient factors and risk for continued hemorrhage should dictate therapy (American Society of Anesthesiologists, 1996).

TRANSFUSION

Compatibility Testing

When the possible need for transfusion is present, an order for a *type and screen* informs blood bank personnel that blood products may be required and initiates two tests to characterize a patient's RBCs. The first evaluation, termed *typing,* mixes commercially available standardized controls with a patient's blood sample to determine her ABO type and Rh phenotype. The second test, or *screen,* combines a patient's plasma sample with control RBCs that express clinically significant RBC antigens. If a patient has formed antibodies to any of these specific RBC surface antigens, then agglutination or hemolysis of the sample is seen.

Typing and screening require about 45 minutes to complete and are valid for 3 days in patients who do receive transfusion. In those who are not transfused, the validity is considerably longer and typically is determined by individual blood banks.

Alternatively, an order to *type and crossmatch* blood products alerts blood bank personnel to designate specific units of blood solely for one individual's use and to test blood in those specific units against the patient's for specific antigen reactions. If blood is needed immediately, however, and a full screen is not possible, then ABO type-specific blood or O-negative blood may be used.

Packed RBCs

Previously, whole-blood transfusion was used commonly to provide RBCs, coagulation factors, and plasma proteins, but this largely has been replaced by component therapy. Packed RBCs are the primary product used for most clinical situations, and concentrated RBC suspensions can be prepared by removing most of the supernatant plasma after centrifugation. One unit of packed RBCs contains the same red cell mass as 1 unit of whole blood at approximately half the volume and twice the hematocrit (70 to 80 percent). One unit of packed RBCs raises the hematocrit approximately 3 volume percent in an adult or increases the hemoglobin level of a 70-kg individual by 1 g/dL (Table 40-7) (Gorgas, 2004).

Table 40-7 Characteristics of Blood Components

Component	Volume, mL	Content	Clinical Response
PRBCs	180â€"200	RBCs	Increases Hb 10 g/L and Hct 3%
Platelets			Increases platelet count
Random-donor unit	50â€"70	5.5×10^{10}	5â€"10 $\times 10^{9}$ /L
Single-donor collection	200â€"400	3.0×10^{11}	>10 $\times 10^{9}$ /L within 1 h and >7.5 $\times 10^{9}$ /L within 24 h postransfusion
FFP	200â€"250	Coagulation factors, including fibrinogen	Increases coagulation factors 2%
Cryoprecipitate	10â€"15	Fibrinogen, factor VIII, vWF	Increases fibrinogen level 0.1 g/L

FFP = fresh-frozen plasma; Hct = hematocrit; Hb = hemoglobin; PRBCs = packed red blood cells; RBCs = red blood cells; vWF = von Willebrand factor.

COMPLICATIONS

Transfusion Reactions

Despite numerous tests for compatibility, adverse reactions to blood products can develop and may include an acute or delayed hemolytic transfusion reaction, febrile nonhemolytic transfusion reaction, or allergic reaction.

Acute Hemolytic Transfusion Reaction

Acute immune-mediated hemolysis usually involves destruction of transfused RBCs by patient antibodies and most commonly results from ABO incompatibility. Symptoms begin within minutes or hours of transfusion and may include chills, fever, urticaria, tachycardia, dyspnea, nausea and vomiting, hypotension, and chest and back pain. In addition, these reactions can lead to acute tubular necrosis or disseminated intravascular coagulopathy, and treatment is directed to these serious complications.

If acute hemolysis is suspected, transfusion should be halted immediately. A sample of the patient's blood should be sent with the remaining donor unit for evaluation in the blood bank. In patients with significant hemolysis, laboratory values will be altered. Specifically, serum haptoglobin levels will be lowered; serum lactate dehydrogenase and bilirubin levels will be increased; and

serum and urine hemoglobin levels will be elevated. Serum creatinine and electrolytes levels and coagulation studies additionally should be ordered.

To prevent renal toxicity, diuresis is prompted with intravenous crystalloids and administration of furosemide or mannitol. Alkalinizing of urine may prevent precipitation of hemoglobin within the renal tubules, and therefore, intravenous bicarbonate also may be given.

In contrast to acute hemolytic transfusion reaction, delayed hemolytic transfusion reactions may develop days or weeks later. Patients often lack acute symptoms, but lowered hemoglobin levels, fever, jaundice, and hemoglobinemia may be noted. Clinical intervention typically is not required in these cases.

Nonhemolytic Transfusion Reactions

Febrile nonhemolytic transfusion reaction is characterized by chills and a greater than 1Â°C rise in temperature and is the most common transfusion reaction. Blood transfusion typically is stopped to exclude a hemolytic reaction, and treatment is supportive. For patients with a previous history of febrile reaction, premedication with an antipyretic such as acetaminophen prior to transfusion is reasonable.

Urticaria alone may develop during transfusion and typically is not associated with serious sequelae. It is generally attributed to an allergic, antibody-mediated response to donor plasma proteins. The transfusion does not need to be stopped, and treatment with an antihistamine, such as diphenhydramine 50 mg orally or intramuscularly, usually is sufficient. Rarely, an anaphylactic reaction may complicate transfusion, and treatment follows that for classic anaphylaxis. (see Table 27-3).

Infection

Infectious complications associated with packed RBC transfusion are uncommon and are listed in Table 40-8. The risk for transmission of HIV and hepatitis B and C virus has diminished over the past decade, and bacterial contamination now stands as a greater infection risk. In addition, emerging infection concerns include transmission of West Nile virus, transfusion-transmitted virus (TTV), hepatitis G, Epstein-Barr virus, and Creutzfeld-Jakob disease (CJD) (Luban, 2005).

Table 40-8 Blood Product Transfusion Risks

Type of Risk/Complication	**Incidence**
Allergic reactions	1:2,000
Transfusion-related acute lung injury	1:4,000
ABO-incompatible transfusion	
Mistransfusion	1:14,000â€“1:18,000
Acute hemolytic reaction	1:6,000â€“1:33,000
Delayed hemolytic reaction	1:2,000â€“11,000
Infections	
Viral	
Hepatitis A	1:1 million
Hepatitis B	1:6,000â€“1:320,000
Hepatitis C	1:1.2 millionâ€“<1:13 million

Human cytomegalovirus (CMV)	1:10â€“1:30
Epstein-Barr virus (EBV)	1:200
Human immunodeficiency virus (HIV)	1:1.4 millionâ€“1:11 million
West Nile virus	1:3,000â€“1:5,000
Bacterial	
Yersinia enterocolitica, Serratia m, Pseudomonas aeruginosa, Enterobacter	1:200,000â€“1:4.8 million
Parasites	
Malaria	1:4 million
Prions	
Creutzfeldt-Jacob disease	Unknown
Immunomodulation/suppression	Unknown

From Strumper-Groves, 2006, with permission

Transfusion-Related Acute Lung Injury (TRALI)

This infrequent but serious complication of blood component therapy is similar clinically to acute respiratory distress syndrome (ARDS). Symptoms develop within 6 hours of transfusion and may include extreme respiratory distress, frothy sputum, hypotension, fever, and tachycardia. Noncardiogenic pulmonary edema with diffuse bilateral pulmonary infiltrates on chest radiography is characteristic (Toy, 2005). Treatment of TRALI is supportive and focuses on oxygenation and blood pressure support (Silliman, 2005; Swanson, 2006).

Platelets

For patients with moderate hemorrhage, RBC transfusion typically is sufficient, but for patients with severe hemorrhage, platelet transfusion also may be indicated. Platelets may be acquired from a single individual during plateletpheresis and are termed *single-donor platelets.* Alternatively, platelets may be derived from random units of whole blood and are referred to as *random-donor platelets.*

Fewer platelets are harvested from a unit of whole blood compared with the amount removed during donor plateletpheresis. Specifically, a single-donor platelet dose contains at least 3×10^{11} platelets in 250 to 300 mL of plasma, and this approximates the dose from six random-donor platelet concentrates. Each random-donor platelet concentrate contain 5.5×10^{10} platelets suspended in approximately 50 mL of plasma. Each concentrate transfused should raise the platelet count by 5 to 10×10^{9} /L, and the usual therapeutic dose is one platelet concentrate per 10 kg of body weight. Five to six concentrates provide a typical adult dose.

Donor plasma must be compatible with recipient erythrocytes because a few RBCs are invariably transfused along with the platelets. Thus, only platelets from D-negative donors should be given to D-negative recipients.

Surgical patients with bleeding usually require platelet transfusion if the platelet count is less than 50×10^{9} /L and rarely require therapy if it is greater than 100×10^{9} /L. With counts between 50 and 100×10^{9} /L, the decision to provide platelet transfusion is based on a patient's risk for additional significant bleeding (American Society of Anesthesiologists, 1996). In patients requiring a large transfusion, a standard 6-unit pack of platelets may be indicated for every 7.5 units of RBCs transfused (Ketchum, 2006).

Fresh-Frozen Plasma

This component is prepared from whole blood or by plasmapheresis and is stored frozen. Approximately 30 minutes are required for the frozen plasma to thaw. One unit contains all coagulation factors, including 2 to 5 mg/mL of fibrinogen in 250 mL of volume. Recommended dosing is 10 to 15 mL/kg.

Fresh-frozen plasma is used commonly as first-line hemostatic therapy in massive hemorrhage because it replaces multiple coagulation factors. It should be considered in a bleeding woman with a fibrinogen level below 1.0 g/L or with abnormal prothrombin and partial thromboplastin times (Cunningham, 2005).

Cryoprecipitate

This component is prepared from fresh-frozen plasma and contains fibrinogen, factor VIII, von Willebrand factor, factor XIII, and fibronectin. Cryoprecipitate was developed and used originally for treatment of hemophilia A and von Willebrand disease. However, specific factor concentrates are now available for these disorders, and thus the clinical indications for cryoprecipitate are limited.

Fresh-frozen plasma provides all coagulation factors and is favored in severe hemorrhage over cryoprecipitate. However, cryoprecipitate is an excellent source of fibrinogen and may be indicated if fibrinogen levels persist below 1.0 g/L despite administration of fresh-frozen plasma, such as in disseminated intravascular coagulopathy (DIC). The dose of cryoprecipitate is usually 2 mL/kg of body weight, and each unit contains about 15 mL volume. One unit should increase the fibrinogen level by 10 mg/dL (Erber, 2006).

ADJACENT ORGAN SURGICAL INJURY

Adequate operating exposure, meticulous surgical technique, and surgical experience are important factors in prevention of injury to surrounding organs during gynecologic surgery. However, these complications may arise especially in cases in which anatomy is distorted or the operating field is obscured by adhesions, blood, or tumor spread.

Ureter

These injuries are uncommon in benign gynecologic surgery, and incidences associated with all hysterectomy approaches range from 0.03 to 6.0 percent (Harkki-Siren, 1998; Ostrzenski, 2003; Visco, 2001). Rates of injury are increased with operations for pelvic organ prolapse and incontinence. Specifically, incidences of obstruction or injury as high as 11 percent during reconstructive surgery for pelvic organ prolapse surgery have been reported (Barber, 2000). Other risk factors include altered pelvic anatomy from malignancy, prior surgery, an enlarged uterus, or adhesions from endometriosis or prior pelvic inflammatory disease (PID).

Ureteral injury may include transection or obstruction following ligation or clamp crush. In addition, trauma to its outer sheath with subsequent disruption of ureteral blood supply can affect its viability. Although the ureter may be injured during a variety of procedures, several surgeries have critical points at which the ureter may be at greater risk. For example, clamping the uterine arteries or suturing the vaginal cuff during hysterectomy; ligating the infundibulopelvic ligament during adnexa removal; suturing the Douglas cul-de-sac or uterosacral ligaments during culdoplasty; and placing suspensory sutures during colposuspension all are associated with increased risk.

Ideally, injuries are recognized intraoperatively because those repaired at the time of initial surgery are associated with improved repair and lower patient morbidity (Neuman, 1991; Sakellariou, 2002). Injury may be visible or may be identified using cystoscopy. Detection with cystoscopy can be aided by intravenous administration of one 5-mL ampule of indigo carmine. This dye gives urine a blue color and improves identification of urine passage through ureteral orifices. Up to 90 percent of unsuspected ureteral injuries and 85 percent of unsuspected bladder injuries may be identified with the use of cystoscopy (Gilmour, 1999, 2006; Gustilo-Ashby, 2006). However, partial ureteral kinking can be missed with this procedure (Dandolu, 2003). Thus, cystoscopy cannot be relied on solely for the diagnosis of ureteral injury. Alternatively, intraoperative ureteral catheterization or intravenous urography may be used to isolate lesions.

Once noted, injuries may be corrected by stenting, end-to-end reanastomosis, or ureteroneocystostomy. These should be performed by surgeons skilled in these operation. Many injuries, however, are unsuspected and diagnosed following surgery. Women may complain of flank pain, fever, and costovertebral angle tenderness. Ureterovaginal fistula, ileus, urine peritonitis, and pyelonephritis may be noted.

To increase early detection, a broader use of intraoperative cystoscopy has been advocated (Ferro, 2003; Vakili, 2005). However, urinary tract injury during most gynecologic procedures is uncommon, and cystoscopy may be reserved for cases with greater risks for ureteral injury.

Bladder

Bladder injury is more frequent than ureteral damage during gynecologic surgery and may include perforation by sutures or laceration. It occurs most commonly during urogynecologic procedures and hysterectomy. Specifically, bladder injury complicates 1 to 2 percent of hysterectomies and is associated more commonly with a vaginal approach (Harris, 1997). Risk factors include prior pelvic reconstructive surgeries and prior cesarean delivery with scarring between the bladder and anterior uterus (Neumann, 2004; Rooney, 2005). Thus, depending on the prior procedure, the bladder may be at greater risk during: (1) initial abdominal entry when incising the anterior parietal peritoneum, (2) dissection within the space of Retzius, (3) dissection of the vaginal epithelium when performing anterior colporrhaphy, or (4) hysterectomy when dissecting the vesicouterine fold, entering the anterior vagina, or suturing the vaginal cuff.

Bladder injury is identified commonly at the time of surgery, and initially, a gush of clear fluid into the operating field may be seen. Laceration may be confirmed with instillation of sterile infant formula through a Foley catheter into the bladder. Leakage of opaque milk aids in identifying a laceration and delineating its borders. Additionally, cystoscopy may be indicated to further define bladder injury, exclude concurrent ureteral injury, or identify sutures placed through the bladder mucosa. If cystoscopy is performed, findings may be more clearly defined if indigo carmine is administered intravenously several minutes prior to the examination.

As with ureteral injury, repair at the primary surgery is preferred and lowers the risk of postoperative vesicovaginal fistula formation. Once ureteral patency is confirmed, the bladder may be closed with a two- or three-layer running closure using a 3-0 absorbable or delayed-absorbable suture (Fig. 40-40). The first layer inverts the mucosa into the bladder, and subsequent layers reapproximate bladder muscularis. Postoperative care requires continuous bladder drainage for 7 to 10 days.

FIGURE 40-40

Cystotomy repair. The primary layer inverts the bladder mucosa with running or interrupted sutures of 3-0 delayedabsorbable or absorbable suture. Second and possibly a third layer approximate the bladder muscularis to reinforce the incision closure. *(From Lee, 1992, with permission.)*

Alternatively, if injury involves errant sutures placed through the bladder mucosa, sutures should be cut. Persistent sutures can lead to cystitis symptoms or stone formation or both.

Bowel

Injury to the bowel infrequently complicates gynecologic surgery, and rates in general lie below 1 percent (Harris, 1997; Makinen, 2001). Complications, however, may be more common in those with adhesions from prior surgery, infection, or endometriosis. Management of enterotomy varies considerably and typically is dictated by the size of injury, skill of the surgeon, and portion of the intestine entered. Short enterotomy wounds into the small intestine may be repaired with a layered closure using fine absorbable suture. During repair, rubber-shod clamps are placed across the intestinal lumen on either side of the wound to prevent spill of contents.

The large intestine carries a greater risk of contamination, but small enterotomies also may be managed as those of the small intestine. For most general gynecologists, larger incisions of either the small or large bowel, however, merit consultation with a general surgeon.

41-1 MIDLINE VERTICAL INCISION

Vertical or transverse incisions both may be used to gain abdominal entry, and each offers particular advantages. Vertical incisions may be midline or paramedian, but of the two, the midline is chosen more often. This incision offers quick entry, minimal blood loss, superior access to the upper abdomen, generous operating room, and the flexibility for easy wound extension if greater space or access is needed.

Preoperative

PATIENT EVALUATION

Before any gynecologic procedure, all women with reproductive ability should be screened for concurrent pregnancy. Although many indicated gynecologic procedures may be performed during pregnancy, re-evaluation of the need and the approach to many operations are affected by concurrent pregnancy. Measurement of either urine or serum beta human chorionic gonadotropin (β-hCG) levels is typically used. In addition, to limit the possibility of an early, undetected luteal-phase conceptus, surgery may ideally be performed during the follicular phase, and an effective contraceptive method should be used until surgery.

As with pregnancy, cervical neoplasia may alter the need or approach to surgical correction of a gynecologic problem. For example, simple (Type 1) hysterectomy performed to treat a benign gynecologic condition will be inadequate treatment to cure most stages of cervical cancer (see Chap. 30, Treatment). Accordingly, women should have current Pap smear screening prior to surgery.

CONSENT

Despite surgical advantages, midline incisions are associated more frequently with greater postoperative pain and increased risk of incisional hernia than low transverse incisions. In addition, risk of bowel injury is present on abdominal entry, especially when extensive adhesions are present. Wound infection may follow any abdominal incision and is discussed in Chapter 3, Clinical Significance and Risks.

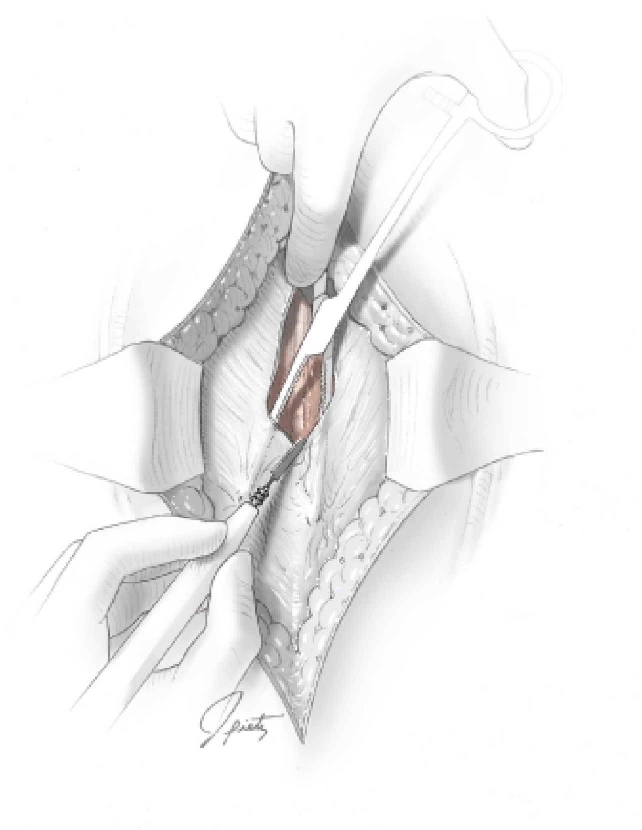
Intraoperative

Surgical Steps

1. **Anesthesia and Patient Positioning.** After administration of adequate regional or general anesthesia, the patient is positioned supine, a Foley catheter is placed, and sterile abdominal prep is completed.

2. **Skin and Subcutaneous Layer.** A midline vertical incision is made sharply beginning 2 to 3 cm above the symphysis pubis and extending cephalad to within 2 cm of the umbilicus (Fig. 41-1.1). In cases that require larger operating space or extensive access to the upper abdomen, the incision may arch around to the left of the umbilicus and continue cephalad as needed. The subcutaneous layers of Camper and Scarpa are incised to reach the fascial layer.

FIGURE 41-1.1



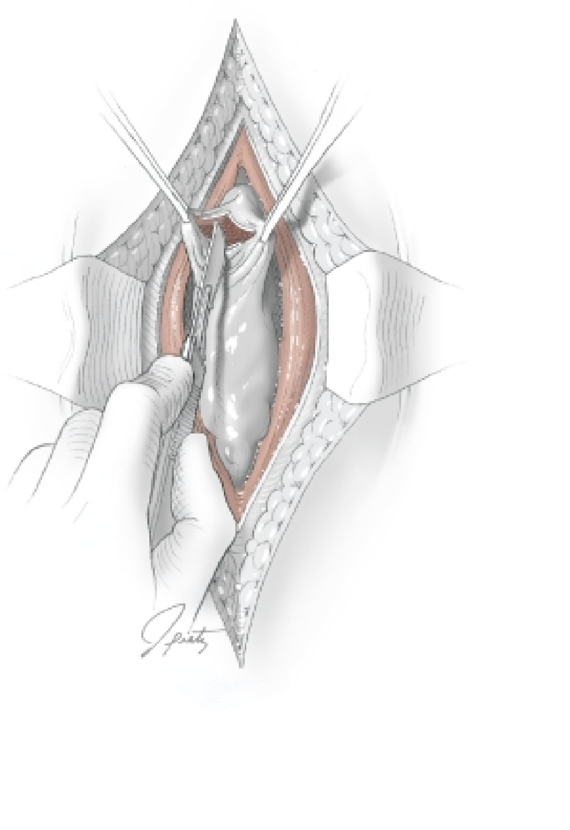
Source: Schorge JO, Schaffer JI, Halvorson LM, Hoffman BL, Bradshaw KD, Cunningham FG: *Williams Gynecology*: http://www.accessmedicine.com

Fascial incision.

3. **Fascia.** Tendinous fibers from the anterior abdominal wall muscles merge in the midline of the abdomen to form the linea alba (see Fig. 38-1). This fascia layer is entered sharply near the midpoint of the incision to avoid potential injury to the bladder inferiorly. This incision is extended cephalad and caudally to mirror the length of the skin incision. During this process, the linea alba may be elevated with fingertips or the ends of a pean clamp to minimize injury to tissues below (see Fig. 41-1.1).

4. **Peritoneum.** The peritoneum is identified between the bellies of the rectus abdominis muscle, grasped with two fine forceps or hemostats, and cut sharply. Similarly, this incision is extended cephalad and caudally (Fig. 41-1.2). Fingers are placed underneath and elevate the peritoneum to prevent bowel injury. As the incision is extended caudally, the bladder dome can be identified by the increasing vascularity and thickness of the peritoneum.

FIGURE 41-1.2



Source: Schorge JO, Schaffer JI, Halvorson LM, Hoffman BL, Bradshaw KD, Cunningham FG: *Williams Gynecology*: http://www.accessmedicine.com

Peritoneal incision.

5. **Operative Field.** Following access to the abdominal cavity, a self-retaining retractor commonly is placed to retract the muscles of the abdominal wall, the bowel, and omentum. Moist laparotomy sponges are placed caudally around the loops of intestines and gently directed cephalad. Upper blades of the retractor assist in holding these loops up and away from the pelvis and operating field. With the pelvic organs exposed, the planned abdominal surgery can proceed.

6. **Wound Closure.** The fascia is closed from one end to the other using a continuous running suture with a 0-gauge delayed-absorbable suture. If the subcutaneous layer measures less than 2 cm, then no closure is necessary. For deeper wounds, interrupted stitches of 4-0 delayed-absorbable suture are used to close this layer. The skin is closed with a subcuticular stitch using 4-0 delayed-absorbable suture or other suitable method.

Postoperative

For most gynecologic surgeries, recovery from the abdominal incision constitutes the greatest portion of postoperative healing. Midline incisions lead to significant pain with ambulation, coughing, and deep breathing. As a result, women undergoing laparotomy are at greater risk of postoperative thrombotic and pulmonary complications. For this reason, prevention of these complications is warranted (see Chap. 39). In addition, return of normal bowel function is commonly slowed, and signs of ileus should be monitored (see Chap. 39, Resumption of Bowel Function).

41-2 PFANNENSTIEL INCISION

The Pfannenstiel, Cherney, and Maylard incisions are transverse abdominal incisions used for gynecologic procedures. Of these, the Pfannenstiel incision is the most commonly used incision for laparotomy in the United States. As discussed in Chapter 38, because the incision follows Langer lines of skin tension, excellent cosmetic results can be achieved. Additionally, decreased rates of postoperative pain, fascial wound dehiscence, and incisional hernia are noted.

Use of the Pfannenstiel incision, however, is often discouraged for cases in which a large operating space is essential or in which access to the upper abdomen may be needed. Moreover, because of the layers created by incision of the internal and external oblique aponeuroses, purulent fluid could collect between these. Therefore, most cases involving abscess or peritonitis require a midline incision.

Preoperative

CONSENT

General risks associated with transverse laparotomy incisions are similar to those for vertical incisions (see Section 41-1, Midline Vertical Incision). However, these incisions also carry risk of nerve injury to the iliohypogastric, ilioinguinal, and femoral nerves (see Chap. 40, Laparotomy). These injuries more commonly involve sensory function and typically are transient.

Intraoperative

Surgical Steps

1. **Anesthesia and Patient Positioning.** After administration of adequate regional or general anesthesia, the patient is positioned supine, a Foley catheter is placed, and sterile abdominal prep is completed.

2. **Skin and Subcutaneous Layer.** About 2 to 3 cm above the symphysis pubis, an 8- to 10-cm transverse incision is made with its lateral margins arching slightly cephalad. The incision is extended deeply with electrosurgical blade through the subcutaneous layer until the anterior rectus sheath is reached. The superficial epigastric vessels lie in the subcutaneous layer within the path of this incision and may be severed during entry (see Fig. 38-2).

3. **Fascia.** The anterior rectus sheath then is incised transversely in the midline. At the level of the incision, the anterior rectus sheath typically is composed of two visible layers, the aponeuroses from the external oblique muscle and a fused layer containing aponeuroses of the internal oblique and transversus abdominis muscles Lateral extension of the anterior rectus sheath incision requires transverse incision of each layer individually (Fig. 41-2.1)

   The superior edge of the fascial incision is grasped with a Kocher clamp on each side of the midline. Traction is directed cephalad and slightly upward.

   In the area superior to the initial incision, the anterior rectus sheath then is separated bluntly or sharply from the underlying rectus muscle (Fig. 41-2.2). The fascia separates easily from the bellies of the rectus muscle but may be densely adhered along the midline. Several smaller perforating nerves and vessels traverse the space between the anterior rectus sheath and rectus muscle. Coagulation of these vessels, while avoiding injury to the nerves, should be undertaken during the separation. On completion of this dissection, a semicircular area with a radius of about 6 to 8 cm has been created. A similar separation is performed in the area inferior to the initial incision.

FIGURE 41-2.1

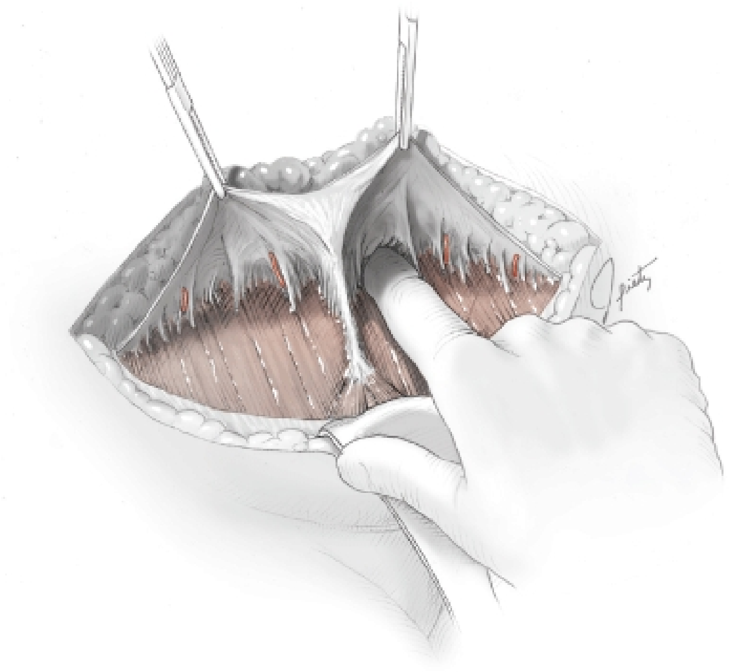
Fascial incision.

FIGURE 41-2.2



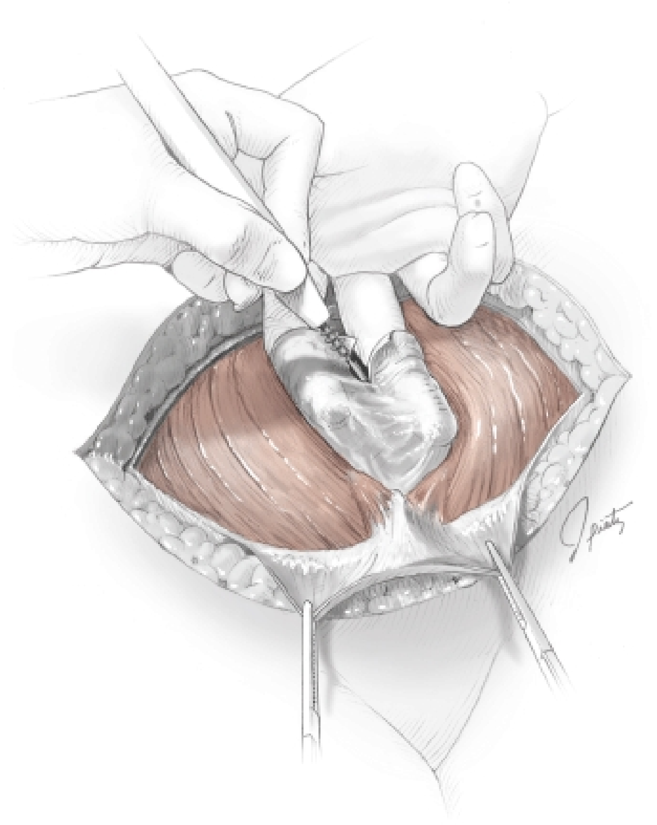
Source: Schorge JO, Schaffer JI, Halvorson LM, Hoffman BL, Bradshaw KD, Cunningham FG: *Williams Gynecology*: http://www.accessmedicine.com

Anterior rectus sheath separation.

4. **Rectus Abdominis Muscle.** The rectus abdominis muscle bellies then are separated along the midline either bluntly or sharply. The pyramidalis muscles, located superficial to the rectus muscle, usually require sharp division at the midline.

5. **Peritoneum.** On separation of the rectus muscle, the thin, filmy peritoneum is identified, grasped with two hemostats, and incised sharply. The peritoneal incision then is extended superiorly and inferiorly (Fig. 41-2.3). Once the abdominal cavity has been entered, the surgeon can proceed with the planned operation.

FIGURE 41-2.3

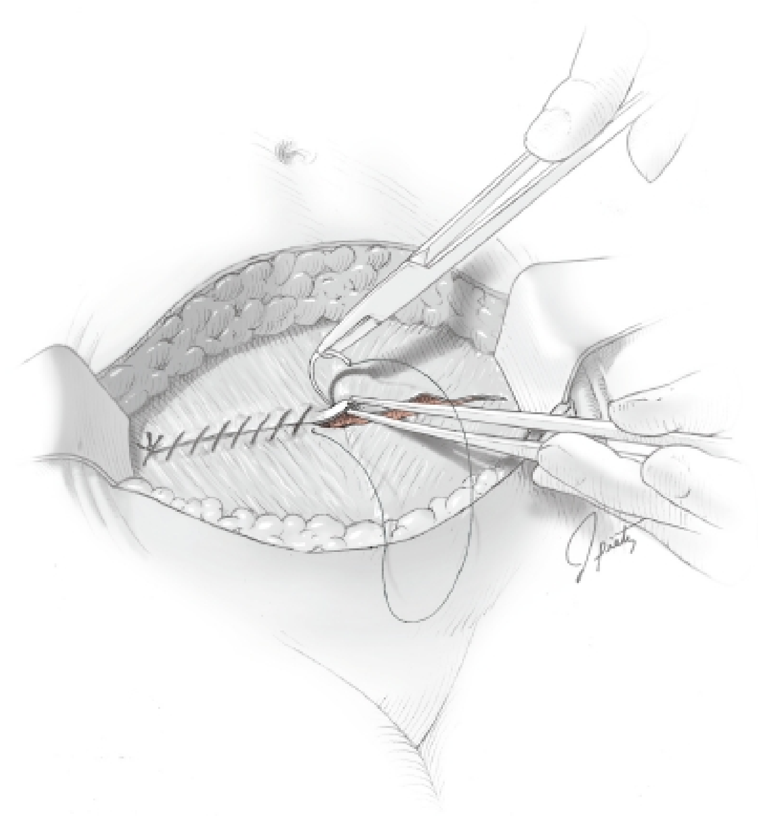


Source: Schorge JO, Schaffer JI, Halvorson LM, Hoffman BL, Bradshaw KD, Cunningham FG: *Williams Gynecology*: http://www.accessmedicine.com

Peritoneal incision.

6. **Wound Closure.** At completion of the intra-abdominal portion of surgery, closure of the incision begins. Closure of the visceral or parietal peritoneum is not encouraged (see Chap. 40, Wound Closure). The fascial layer is closed in a running suture using 0-gauge delayed-absorbable suture (Fig. 41-2.4). In patients with a greater than 2-cm subcutaneous layer, closure of this layer can decrease rates of wound infection and dehiscence. The skin may be closed with staples or a subcuticular stitch of 4-0 delayed-absorbable suture.

FIGURE 41-2.4



Source: Schorge JO, Schaffer JI, Halvorson LM, Hoffman BL, Bradshaw KD, Cunningham FG: *Williams Gynecology*: http://www.accessmedicine.com

Fascial closure.

Postoperative

The postoperative course for low transverse incisions follows that described for midline incisions (see Section 41-1, Midline Vertical Incision).

41-3 CHERNEY INCISION

The Cherney incision is a tranverse abdominal incision that is similar to the Pfannenstiel incision in its early steps. After the anterior rectus sheath is opened, however, the tendons of the rectus and pyrimadalis muscles are transected 1 to 2 cm above their insertion into the symphysis pubis. These muscles then are lifted cephalad to provide access to the peritoneum.

This incision offers greater operating space as well as access to the space of Retzius and therefore may be a primary choice in cases when these requirements are anticipated. Additionally, Pfannenstiel incisions may be converted to Cherney incisions when an unexpected need for additional operating space arises.

Preoperative

Preparation and consent prior to a Cherney incision are similar to those for a Pfannenstiel incision (see Section 41-2, Pfannenstiel Incision).

Intraoperative

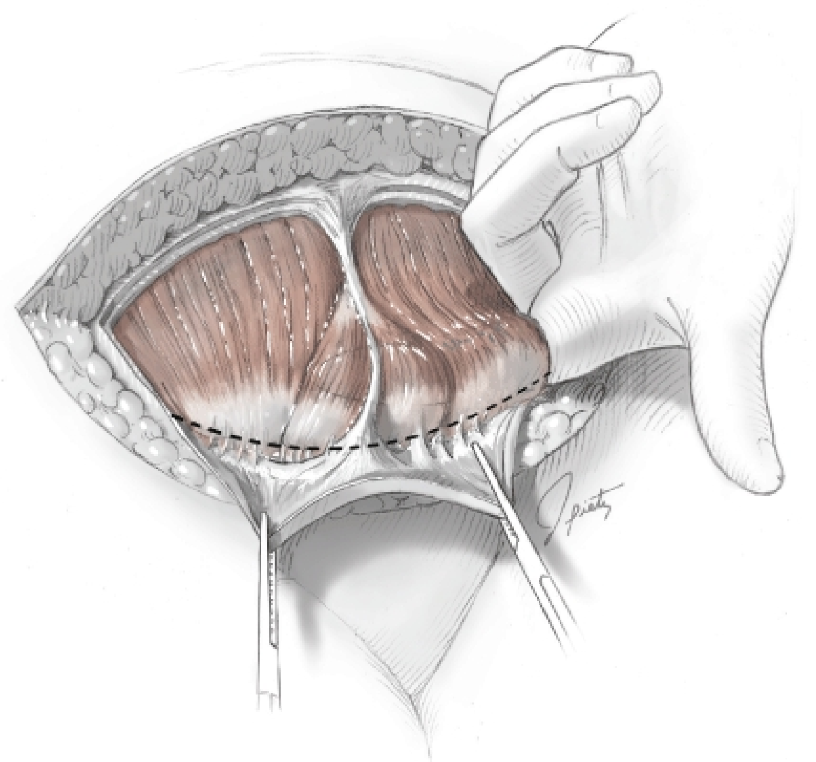
Surgical Steps

1. **Initial Steps.** The initial steps mirror those of the Pfannenstiel incision (see Section 41-2, Pfannenstiel Incision, steps 1 through 3). After lateral extension of the fascial incision, however, the techniques diverge.

2. **Fascia.** The fascial opening reveals the rectus abdominis muscles and the smaller, triangular-shaped pyrimadalis muscles, which lie more caudad and superficial. Cephalad to the symphysis pubis, fingers are insinuated underneath the rectus muscle tendons into the space of Retzius. This dissection begins laterally and extends toward the midline. Finger are insinuated in this manner to protect the underlying bladder from laceration during tendon transection.

   The tendons of both muscles then are transected 1 to 2 cm above the symphysis pubis (Fig. 41-3.1). The muscles are lifted cephalad. The peritoneum is grasped with two hemostats and is incised sharply. This incision is extended vertically. Once the abdominal cavity has been accessed, the planned surgery can proceed. If surgery is planned in the space of Retzius, and not intra-abdominally, then the peritoneum is not incised.

FIGURE 41-3.1

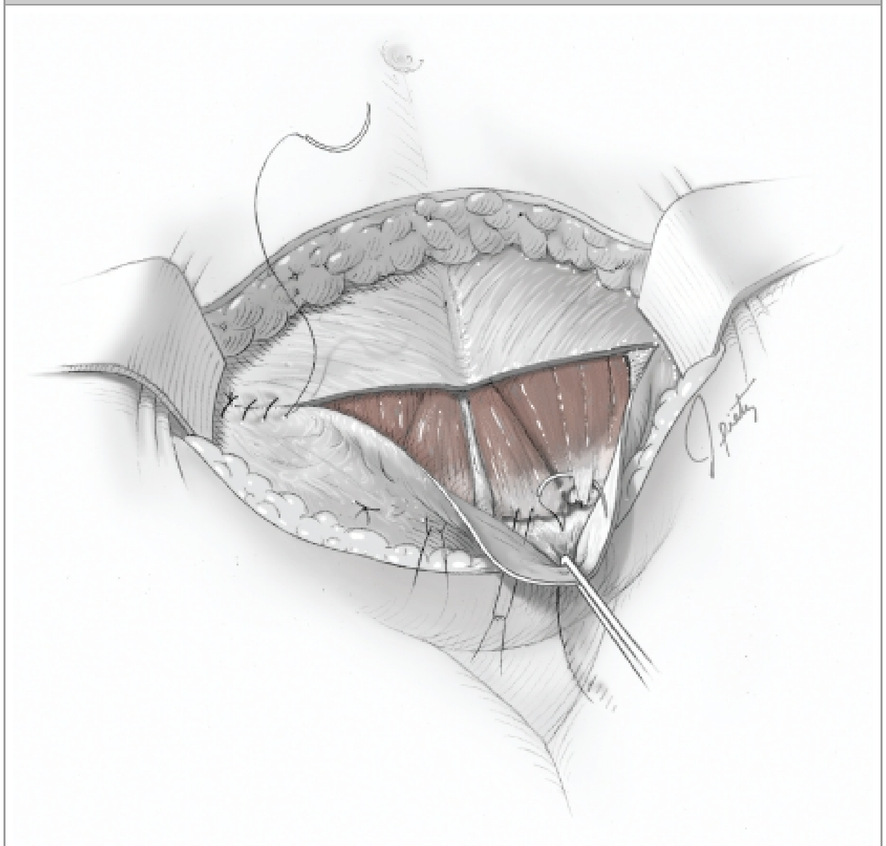


Source: Schorge JO, Schaffer JI, Halvorson LM, Hoffman BL, Bradshaw KD, Cunningham FG: *Williams Gynecology*: http://www.accessmedicine.com

Tendon transection.

3. **Wound Closure.** During wound closure, the cut ends of the rectus muscle tendons are affixed with interrupted sutures of 0-gauge delayed-absorbable sutures to the undersurface of the inferior fascia (Fig. 41-3.2). To avoid osteitis pubis or osteomyelitis, the tendons should not be affixed directly to the symphysis pubis. The fascia then is closed in a running suture using 0-gauge delayed-absorbable suture. The remaining incision closure follows that for the Pfannenstiel incision.

FIGURE 41-3.2



Source: Schorge JO, Schaffer JI, Halvorson LM, Hoffman BL, Bradshaw KD, Cunningham FG: *Williams Gynecology*: http://www.accessmedicine.com

Wound closure.

Postoperative

The postoperative course for low transverse incisions follows that described for midline incisions (see Section 41-1, Midline Vertical Incision).

41-4 MAYLARD INCISION

The Maylard incision differs mainly from the Pfannenstiel and Cherney incisions in that the bellies of the rectus abdominis muscle are transected. The main advantage to this incision is the larger operating space it affords. Therefore, it is selected often for cases in which greater access to the pelvis is needed. The Maylard incision is technically more difficult because it requires isolation and ligation of the inferior epigastric arteries. It also has been used infrequently because of concerns regarding greater postoperative pain, decreased abdominal wall strength, longer operating times, and increased febrile morbidity. Randomized studies, however, have not supported these concerns (see Chap. 40, Surgical Incisions).

Preoperative

Preparation and consent prior to a Cherney incision are similar to those for a Pfannenstiel incision (see Section 41-2, Pfannenstiel Incision).

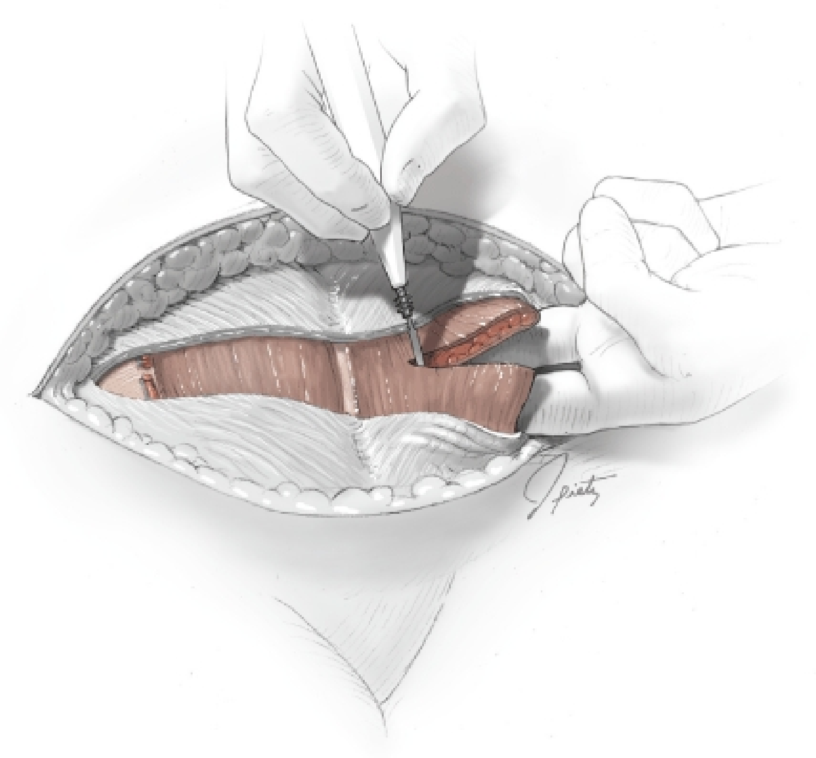
Intraoperative

Surgical Steps

1. **Initial Steps.** The initial steps mirror those of the Pfannenstiel incision (see Section 41-2, Pfannenstiel Incision, steps 1 through 3). After lateral extension of the fascial incision, however, the techniques diverge. The inferior epigastric artery and vein lie posterolateral to the bellies of the rectus abdominis muscle (see Figs. 38-2 and 38-3). Bilaterally, these vessels are identified, ligated, and transected. This step avoids their later laceration and hemorrhage when the rectus muscle is transected.

2. **Rectus Abdominis Muscle.** The rectus abdominis muscle is dissected bluntly away from the underlying peritoneum. The surgeon's fingers are placed behind the bellies of the rectus muscle, and this muscle then is transected using an electrosurgical blade (Fig. 41-4.1). Prior to transection, unlike the Pfannenstiel incision, the anterior rectus sheath should not be dissected away from the underlying rectus muscle. On the contrary, following muscle transection, to improve muscle reapproximation during incision closure, simple interrupted or mattress sutures using 0-gauge delayed-absorbable suture are placed 1 to 2 cm from the cut edge of the muscle and fascia to reinforce the anterior sheath attachment to the rectus muscle. This is performed on both the cephalad and caudad sections of the transected muscle (Fig. 41-4.2).

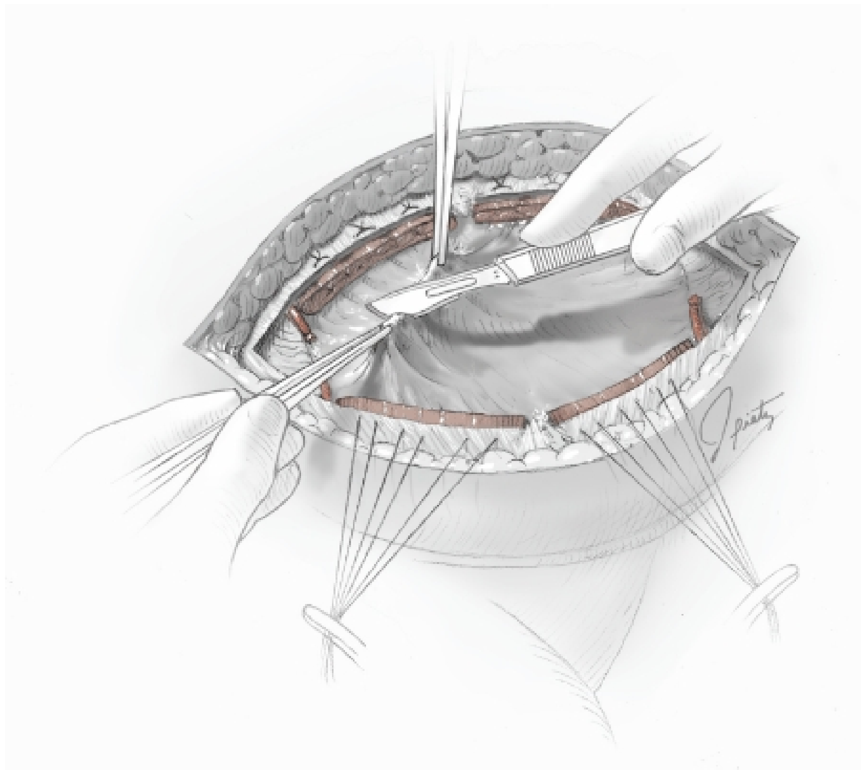
FIGURE 41-4.1



Source: Schorge JO, Schaffer JI, Halvorson LM, Hoffman BL, Bradshaw KD, Cunningham FG: *Williams Gynecology*: http://www.accessmedicine.com

Muscle transection.

FIGURE 41-4.2



Source: Schorge JO, Schaffer JI, Halvorson LM, Hoffman BL, Bradshaw KD, Cunningham FG: *Williams Gynecology*: http://www.accessmedicine.com

Suture placement and peritoneal incision.

3. **Peritoneum.** The peritoneum is grasped with two hemostats and incised sharply. Once created, the peritoneal incision is extended laterally. After obtaining access to the cavity, the planned abdominal surgery can proceed.

4. **Wound Closure.** At incision closure, the fascia is closed with a running suture using 0-gauge delayed-absorbable suture. Closing the fascia adequately reapproximates the transected muscles fibers, and therefore, the divided muscles bellies are not sutured directly together. The remaining incision closure follows that for the Pfannenstiel incision.

Postoperative

The postoperative course for low transverse incisions follows that described for midline incisions (see Section 41-1, Midline Vertical Incision).

41-5 HYMENECTOMY

Imperforate hymen results from failure of the hymen to canalize during the perinatal period. Most imperforate hymens are diagnosed after they have become symptomatic, usually during adolescence. Accordingly, the indications for hymenectomy may include complaints of amenorrhea, pain, abdominal mass, and urinary and defecation dysfunction. The diagnostic evaluation of these symptoms prior to surgery is discussed in Chapter 18, Description and Patient Presentation.

Less frequently, an asymptomatic imperforate hymen may be found during childhood. If there is no associated mucocoele, these lesions can be managed expectantly. Elective hymenectomy then can be performed during puberty but prior to menarche to avoid the development of hematometra or hematocolpos. At this developmental stage, the presence of estrogen can aid surgical repair and healing.

Preoperative

CONSENT

Hymenectomy is a simple gynecologic procedure, and most patients recover with no short- or long-term complications. Uncommonly, the hymeneal edges may re-epithelialize, and a repeat procedure may be required (Joki-Erkkila, 2003; Liang, 2003).

PATIENT PREPARATION

Conflicting opinions exist as to the need for prophylactic antibiotics, and little evidence exists to support either view (Adams-Hillard, 2005; Anania, 1994). If employed, intravenous antibiotics with polymicrobial coverage are given just prior to surgery.

Intraoperative

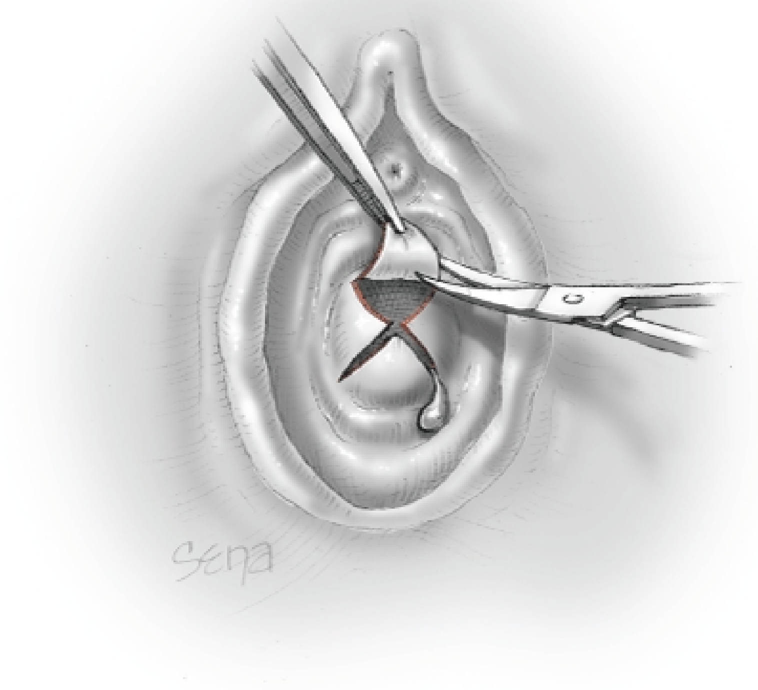
Surgical Steps

1. **Anethesia and Patient Positioning.** Hymenectomy typically is performed as a day-surgery procedure using general anesthesia. The patient is placed in the dorsal lithotomy position, the bladder is drained, and a sterile perineal prep is performed.

2. **Hymen Incision.** To avert injury to the urethra anteriorly and to the rectum posteriorly, the surgeon avoids creating pure vertical and horizontal incisions. Instead, a cruciate incision is made anteroposteriorly from 10 to 4 o'clock and from 2 to 8 o'clock into the hymeneal membrane (Fig. 41-5.1). Immediately, a stream of dark menstrual blood in the case of hematocolpos or mucoid fluid in the case of mucocolpos will follow.

   The hymeneal leaflets then are trimmed sharply from the hymeneal ring. The leaflets are not cut too close to the vaginal epithelium. This avoids increased scarring at the hymeneal ring.

FIGURE 41-5.1



Trimming hymenal leaflets.

3. **Irrigation.** The vagina is irrigated copiously using a sterile saline solution and bulb syringe.

4. **Suturing.** The cut edges of the leaflet bases then are oversewn with interrupted sutures using 3-0 or 4-0 delayed-absorbable suture, A ring of sutures is created (Fig. 41-5.2). A running interlocking suture is avoided to minimize circumferential narrowing of the introitus (Adams-Hillard, 2005).

   Intraoperative evaluation or manipulation of the upper vagina, cervix, and uterus is discourgaged. The walls of these organs may have been thinned by hematocolpos or hematometra and may be at greater risk for perforation.

FIGURE 41-5.2

Suturing leaflet bases.

Postoperative

Following surgery, the patient may use oral as well as topical analgesics, such as 2-percent lidocaine jelly. Local wound care includes twice daily sitz baths. The patient is counseled that retained fluid may continue to drain from the uterus and vagina for several days following surgery. At 1 to 2 weeks following surgery, the introitus is inspected for patency and assessment of healing.

41-6 BARTHOLIN GLAND DUCT INCISION AND DRAINAGE

Bartholin gland duct cysts and abscesses are common vulvar masses encountered routinely in office gynecology (see Chap. 4, Bartholin Gland Duct Cyst and Abscess). Bartholin duct cysts typically measure 1 to 4 cm in diameter and are most commonly asymptomatic. Patients with larger cysts, however, may complain of vaginal pressure or dyspareunia. In contrast, patients with gland abscesses typically present with complaints of rapid unilateral vulvar enlargement and significant pain. Classically, a fluctuant mass is found either on the right or left side of the introitus, external to the hymenal ring, and at the lower aspects of the vulva.

Bartholin cysts or abscesses result from ductal opening obstruction followed by accumulation of mucus or pus within the duct. Bartholin gland duct abscesses are polymicrobial infections, and *Bacteroides* species, *Peptostreptoccus* species, *Escherichia coli,* and *Neisseria gonorrhoeae* are found commonly on culture of purulent drainage. Less typically, *Chlamydia trachomatis* may be involved (Bleker, 1990; Saul, 1988; Tanaka, 2005). Rarely, obstruction of this duct can develop following vaginal surgeries such as

posterior colporrhaphy or as a result of Bartholin gland cancer (Peters, 1998).

Incision and drainage (I&D) alone may give immediate but temporary relief. However, unless a new duct ostium is created, the incised edges following I&D will seal, and mucus or pus will re-accumulate. Therefore, I&D with subsequent steps to create a new ostium are surgical goals (Friedrich, 1983).

Permanent resolution of the cyst or abscess is common following either marsupialization or I&D with Word catheter placement. If obstruction re-occurs, however, repeating either of these procedures is preferable to gland excision for most patients. Bartholinectomy, as discussed next, carries significantly more morbidity than either of these procedures.

Preoperative

CONSENT

Repeated obstruction of the Bartholin gland duct following initial I&D is not uncommon during the weeks and months following drainage. Patients should be aware of the possible need to repeat the procedure should the duct obstruct again.

Intraoperative

INSTRUMENTS

As noted, the goal of Bartholin gland I&D is to empty the cystic cavity and create a new accessory epithelialized tract for gland drainage. For this purpose, a Word catheter (Milex Products, Inc., Chicago, IL) is used. Named after Dr. Buford Word, this catheter appears similar to a small, no. 10 French Foley catheter (Word, 1964). Word catheters are constructed of a 1-in latex tube stem that has an inflatable balloon at one end and a saline-injection hub at the other (Fig. 41-6.1)

FIGURE 41-6.1

Source: Schorge JO, Schaffer JI, Halvorson LM, Hoffman BL, Bradshaw KD, Cunningham FG: *Williams Gynecology*: http://www.accessmedicine.com

Word catheter. (Courtesy of J. Steven Willard.)

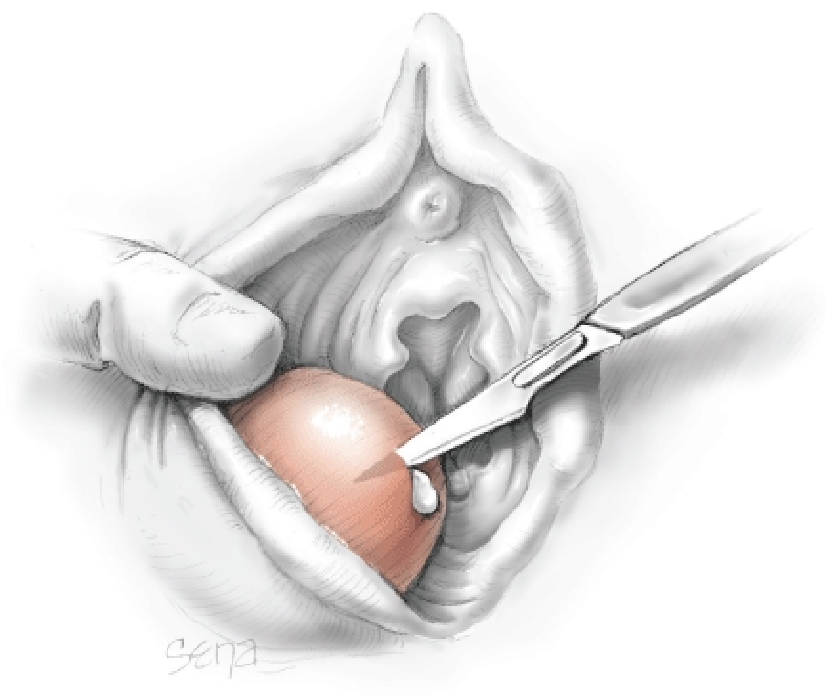
Surgical Steps

1. **Analgesia and Patient Positioning.** Most procedures are performed as an outpatient procedure in the office or emergency room. The patient is placed in the dorsal lithotomy position, and the wound is cleaned with a povidone-iodine solution (Betadine, Purdue Frederick Company, Norwalk, CT) or other suitable antiseptic agent. Local analgesia is sufficient for most cases and can be obtained by infiltrating the skin overlying the planned incision with an aqueous 1-percent lidocaine solution.

2. **Drainage.** A 1-cm incision is made using a scalpel with a no. 11 blade to pierce the skin and underlying cyst or abscess (Fig. 41-6.2). The incision should be made along the inner surface of the cyst or abscess and placed outside and parallel to the hymen at 5 or 7 o'clock on the surface of the vulva. This position mimics the normal anatomy of the gland duct opening and avoids creation of a fistulous tract to the outer surface of the labia majorum (see Fig. 38-27) (Hill, 1998). Cultures for *N gonorrhoeae* and *C trachomatis* can be obtained from spontaneously extruded pus. Mucus drained from a Bartholin cyst need not be cultured.

   The tip of a small hemostat is placed within the drained cavity, and the tips are opened and closed to lyse adhesions and open loculations of pus or mucus within the cavity.

FIGURE 41-6.2



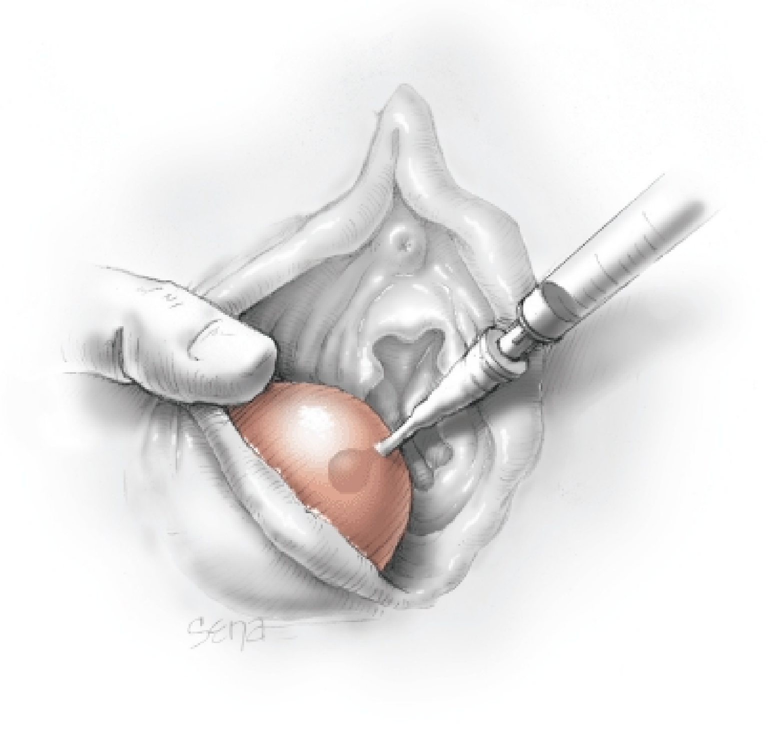
Source: Schorge JO, Schaffer JI, Halvorson LM, Hoffman BL, Bradshaw KD, Cunningham FG: *Williams Gynecology*: http://www.accessmedicine.com

Abscess or cyst incision.

3. **Word Catheter Placement.** The tip of a deflated Word catheter is placed within the empty cyst cavity. A syringe is used to inject 2 to 3 mL of sterile saline through the port of the catheter to inflate the catheter's balloon. The balloon is inflated to reach a diameter that will prohibit the catheter from falling out of the incision (Fig. 41-6.3).

   The hub of the Word catheter then can be tucked inside the vagina to prevent it from being dislodged by traction from perineal movement.

FIGURE 41-6.3



Source: Schorge JO, Schaffer JI, Halvorson LM, Hoffman BL, Bradshaw KD, Cunningham FG: *Williams Gynecology*: http://www.accessmedicine.com

Word catheter in place.

Postoperative

Abscesses typically are surrounded by significant cellulitis, and in such cases, antibiotics are warranted. Antibiotics should be broad spectrum to treat a polymicrobial infection with aerobes and anaerobes (Omole, 2003).

Patients are encouraged to soak in warm tub baths twice daily. Coitus should be avoided for patient comfort and to prevent Word catheter removal. Ideally, the catheter is left in place for 4 to 6 weeks. Often, however, a catheter will be dislodged before this time. There is no need to try and replace the catheter if displaced, and attempts to reinsert it typically are not possible due to cavity closure.

41-7 MARSUPIALIZATION

High recurrence rates follow simple incision and drainage (I&D) of a Bartholin duct cyst or abscess. As noted earlier, a new duct ostium must be created to prevent the incised edges from adhering and allowing mucus or pus to re-accumulate. For this reason, marsupialization was developed as a means to create a new accessory tract for gland drainage (Jacobson, 1950; Matthews, 1966).

With introduction of the Word catheter, however, use of marsupialization has declined. Word catheter placement following I&D offers several advantages over marsupialization, and recurrence rates are equal (Blakely, 1966; Jacobson, 1960). Marsupialization requires a greater degree of analgesia, a larger incision, placement of sutures, and longer procedure time.

Preoperative

CONSENT

The consent for marsupialization mirrors that for Bartholin gland I&D. Accordingly, patients should be aware of the risk for repeated obstruction of the Bartholin gland duct following marsupialization. Patients should be aware of the possible need to repeat the procedure if ductal obstruction recurs.

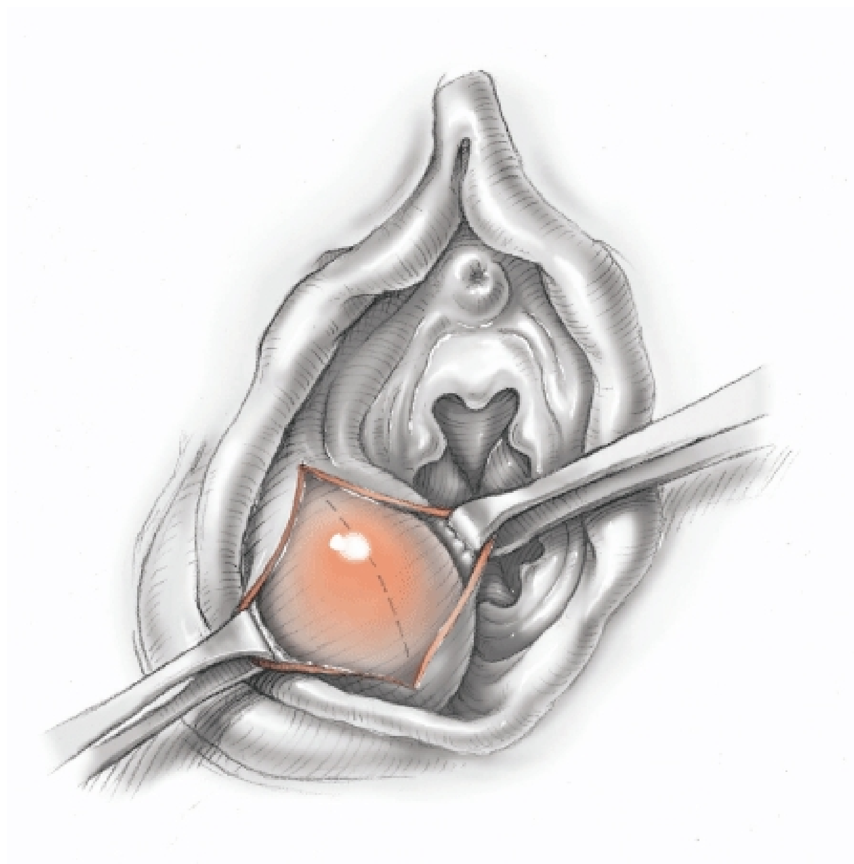
Intraoperative

Surgical Steps

1. **Anesthesia and Patient Positioning.** Marsupialization is an outpatient procedure typically performed in an operating suite using a unilateral pudendal nerve block or general anesthesia. Some authors, however, have described performance of the procedure in an emergency room setting (Downs, 1989). The patient is placed in the dorsal lithotomy position, and the vagina and vulva are surgically prepared.

2. **Skin Incision.** A vertical incision measuring 2 to 3 cm is created using a scalpel with either a no. 10 or no. 15 blade. The incision is made on the vestibule near the medial edge of the labia minora and approximately 1 cm lateral and parallel to the hymenal ring (Fig. 41-7.1). Care is taken to incise the skin but not to puncture the underlying cyst wall.

FIGURE 41-7.1



Source: Schorge JO, Schaffer JI, Halvorson LM, Hoffman BL, Bradshaw KD, Cunningham FG: *Williams Gynecology*: http://www.accessmedicine.com

Skin incision.

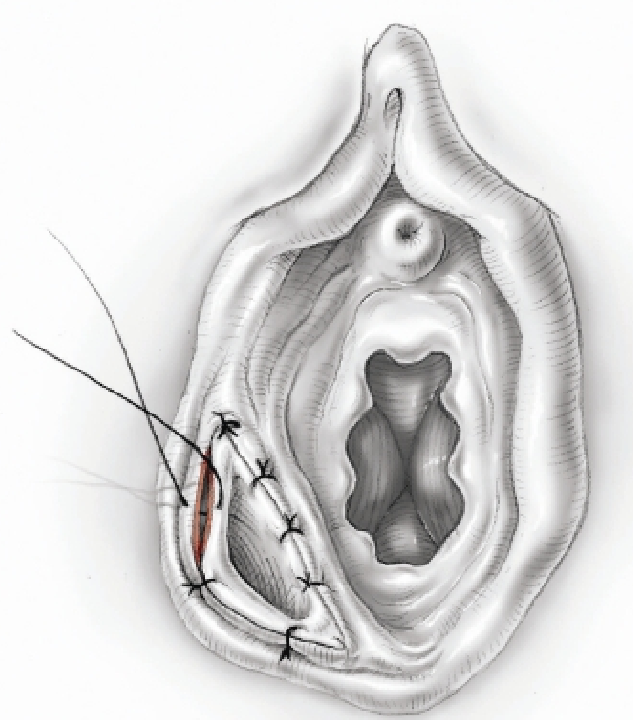
3. **Cyst Incision.** The cyst wall then is incised with a scalpel, and the incision is extended with scissors. Allis clamps then are

placed on the superior, inferior, right, and left lateral edges. Each clamp should grasp and contain the skin and cyst wall edges. These clamps then are fanned out.

The tip of a small hemostat is placed within the drained cavity, and the tips are opened and closed to lyse adhesions and open loculations within it. The cavity is rinsed with sterile saline, and suction is used to remove remaining saline and blood prior to wound closure.

4. **Wound Closure.** The edge of the cyst wall is sutured to its adjacent skin edge with interrupted sutures using 2-0 or 3-0 delayed-absorbable suture (Fig. 41-7.2).

FIGURE 41-7.2



Source: Schorge JO, Schaffer JI, Halvorson LM, Hoffman BL, Bradshaw KD, Cunningham FG: *Williams Gynecology*: http://www.accessmedicine.com

Cyst wall sutured open.

Postoperative

Cool packs during the first 24 hours following surgery can minimize pain, swelling, and hematoma formation. After this time, warm sitz baths, once or twice daily, are suggested for pain relief and wound hygiene.

Patients may be seen within the first week following surgery to ensure that ostium edges have not adhered to each other (Novak, 1978). Within 2 to 3 weeks, the wound shrinks to create a duct opening typically 5 mm or less in size. Recurrence rates following marsupialization are low, and Jacobson (1960) noted only 4 recurrences in his series of 152 patients.

41-8 BARTHOLINECTOMY

Most Bartholin gland duct cysts can be managed with incision and drainage (I&D) or with marsupialization. Symptomatic cysts, however, that recur repeatedly and refill following I&D or marsupialization are typical candidates for excision. Moreover, massive cysts or multilocular cysts may be best managed with excision.

Many authors have suggested excision of all Bartholin gland cysts in women older than age 40 to exclude cancer in the gland. However, a study by Visco and Del Priore (1996) suggests that the morbidity of gland excision may not be justified for this rare cancer. Instead, they recommend I&D of the cyst with biopsy of the cyst wall.

Preoperative

CONSENT

Because of the rich venous plexus of the vestibular bulb, significant bleeding can be encountered during bartholinectomy (see Fig. 38-27). In addition, gland excision can be associated with other morbidities, such postoperative wound cellulitis, hematoma formation, failure to remove the entire cyst wall with risk of recurrence, and pain or dyspareunia or both from postoperative scarring.

PATIENT PREPARATION

These cysts should be excised in the absence of concurrent abscess or surrounding cellulitis. Therefore, antibiotic administration typically is not required.

Intraoperative

Surgical Steps

1. **Analgesia and Patient Positioning.** Excision of most Bartholin cysts is performed as an outpatient procedure, in an operative suite, and under general anesthesia. The patient is placed in the dorsal lithotomy position, and a vaginal and perineal prep is performed.

2. **Skin Incision.** A gauze sponge held by a ring forceps is placed inside the vagina by an assistant, and pressure is directed outward along the posterior aspect of the cyst. This pushes the full extent of the cyst forward. The surgeon's fingers retract the labia minora laterally to expose the anterior surface of the cyst.

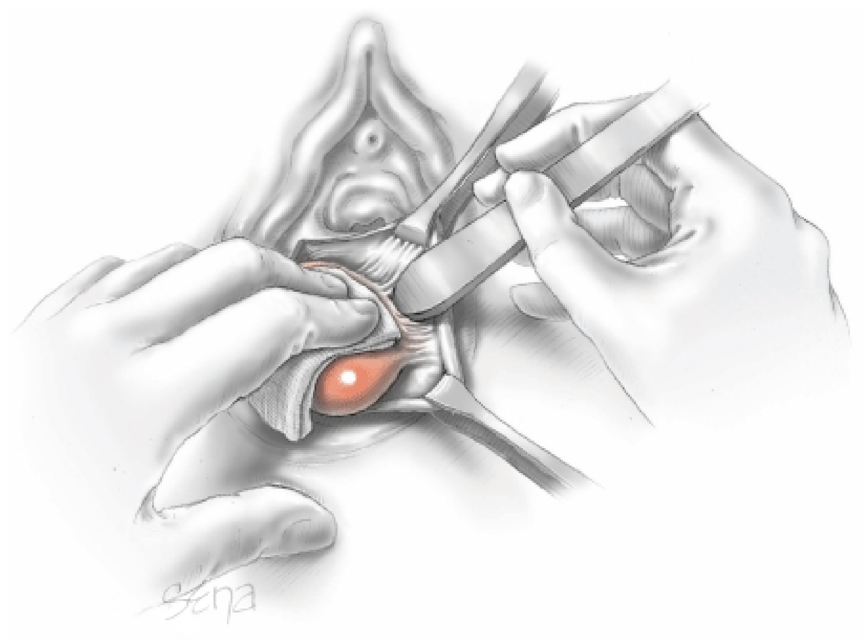
   A linear incision that extends the length of the cyst is made on the vestibule near the medial edge of the labia minora and approximately 1 cm lateral and parallel to the hymenal ring. Care is taken to incise the skin but not to puncture the underlying cyst wall. Allis clamps are placed on the medial skin edges and fanned out medially toward the contralateral labia.

3. **Cyst Dissection.** The greatest vascular structure supplying these cysts is located at the posterosuperior aspect of these cysts. For this reason, dissection should begin at the lower cyst pole and be directed superiorly.

   The inferomedial cyst wall is bluntly and sharply dissected away from the surrounding tissue (Fig. 41-8.1). Dissection planes should be kept close to the cyst wall to avoid bleeding from the venous plexus of the vestibular bulb and to avoid injury to the rectum. Because the lower-most pole of a Bartholin gland duct cyst may extend to lie adjacent to the rectum, the rectum can be entered accidentally during dissection. Placing a finger at times in the rectum can help to orient the surgeon to the spatial relationship between the two.

   Allis clamps then are placed on the lateral skin edges and fanned out laterally, and dissection is performed near the inferolateral cyst wall.

FIGURE 41-8.1

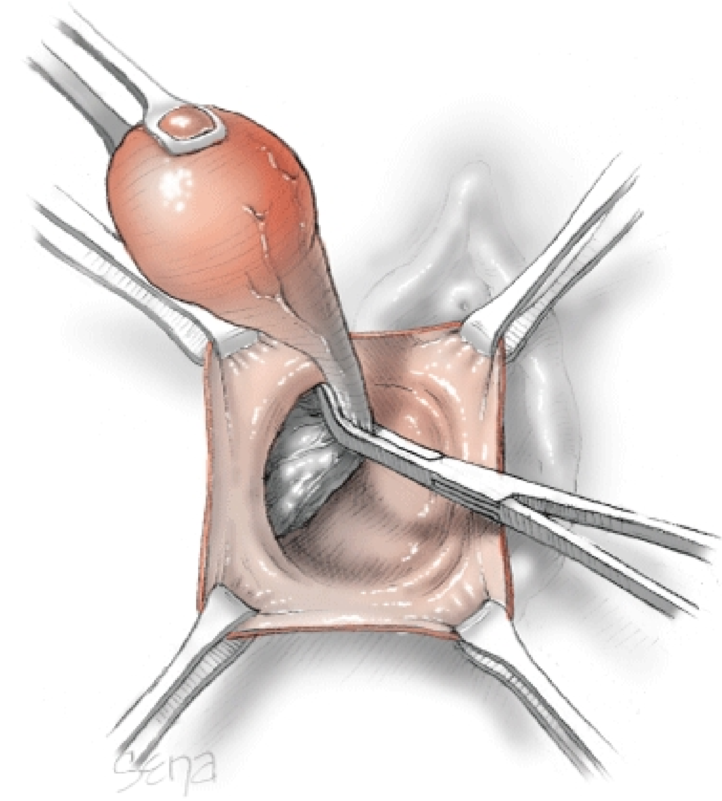


Source: Schorge JO, Schaffer JI, Halvorson LM, Hoffman BL, Bradshaw KD, Cunningham FG: *Williams Gynecology*: http://www.accessmedicine.com

Cyst dissection.

4. **Vessel Ligation.** As dissection is completed superiorly, the main vascular bundle to the cyst is identified and clamped with a hemostat. The bundle is cut and ligated with 3-0 delayed-absorbable or chromic suture (Fig. 41-8.2).

FIGURE 41-8.2



Source: Schorge JO, Schaffer JI, Halvorson LM, Hoffman BL, Bradshaw KD, Cunningham FG: *Williams Gynecology*: http://www.accessmedicine.com

Vessel ligation.

5. **Wound Closure.** The remaining cyst bed is closed in layers with running or interrupted sutures of 3-0 delayed-absorbable suture. Typically, two layers are required prior to skin closure, but in the case of large or vascular cyst beds, additional layers may be required. The skin is approximated with a running subcuticular suture of 4-0 delayed-absorbable suture.

Postoperative

Cool packs during the first 24 hours following surgery can minimize pain, swelling, and hematoma formation. After this time, warm sitz baths, once or twice daily are suggested for pain relief and wound hygiene.

41-9 VESTIBULECTOMY

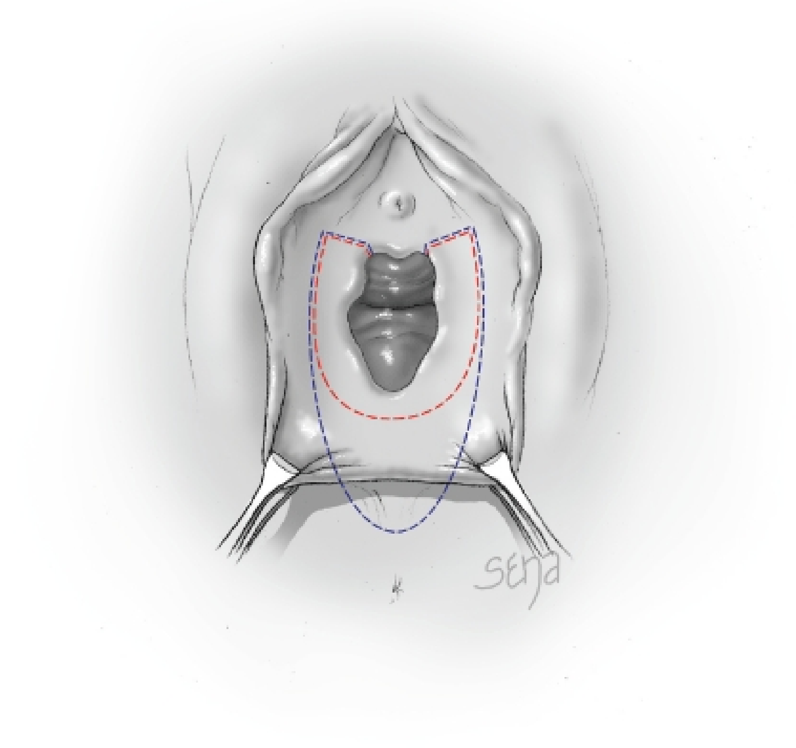
Anatomically, the vestibule extends along the inner labia minora from the clitoris to the fourchette (see Fig. 38-26). Additional borders include the hymenal ring and Hart line, which lies along the inner labia minora and demarcates the boundary between skin and mucosa. For some women, inflammation in this region can lead to vulvodynia and dyspareunia.

Most cases of vulvodynia are managed conservatively, but for refractory cases, three surgeries have been employedâ€”vestibuloplasty, vestibulectomy, and perineoplasty (see Chap. 4, Surgical Therapy) (Edwards, 2003). Vestibuloplasty involves denervation of the vestibule by incision, undermining, and then closure of the mucosa, but without excision of the painful epithelium. It generally has been found to be ineffective (Bornstein, 1995).

Alternatively, vestibulectomy incorporates excision of vestibular tissue (Fig. 41-9.1). Incisions extend from the periurethral area down to the superior edge of the perineum and include the fourchette. The incisions are carried laterally along Hart line and

medially should excise the hymen. In sum, mucous membrane, hymen, and minor vestibular glands are removed. Bartholin ducts are transected. Following excision, the vaginal mucosa is mobilized and pulled distally to cover the defect. In certain cases, a modified vestibulectomy is sufficient and only extends partially up the inner labia minora, well short of the periurethral area (Haefner, 2000; Lavy, 2005).

FIGURE 41-9.1



Source: Schorge JO, Schaffer JI, Halvorson LM, Hoffman BL, Bradshaw KD, Cunningham FG: *Williams Gynecology*: http://www.accessmedicine.com

Incisions for vestibulectomy *(red)* and perineoplasty *(blue)* .

Perineoplasty is the most extensive of the three procedures and extends from just below the urethra to the perineal body, usually terminating above the anal orifice. Similarly, following tissue resection, the vaginal epithelium is advanced to cover the defect. Although used most commonly to treat vulvodynia, perineoplasty also may treat fourchette fissuring and its associated pain caused by lichen sclerosis (Kennedy, 2005; Rouzier, 2002).

Preoperative

PATIENT EVALUATION

The most important factor for surgical success in treating vulvar pain is identifying the proper candidate (see Chap. 4, Vulvodynia). For example, vaginismus coexists in approximately half of patients with vulvodynia and, when present, is associated with lower rates of postoperative pain relief (Goldstein, 2005).

Prior to administration of anesthesia, the patient should undergo testing with a cotton swab to outline the areas of pain. These areas are marked with permanent marker prior to surgery to delineate the extent of excision (Haefner, 2005). Importantly, all sensitive areas should be removed, even those adjacent to the urethra; otherwise, tender foci that should have been resected as part of the primary operation may remain (Bornstein, 1995).

CONSENT

Vestibulectomy and perineoplasty are effective in treating vulvodynia, and in 80 to 90 percent of patients, pain either improves or resolves (Bornstein, 1999; McCormack, 1999; Schneider, 2001). Complications are infrequent but may include bleeding, infection, wound separation, Bartholin duct cyst formation, anal sphincter weakness, vaginismus, and vaginal stenosis (Haefner, 2000).

Intraoperative

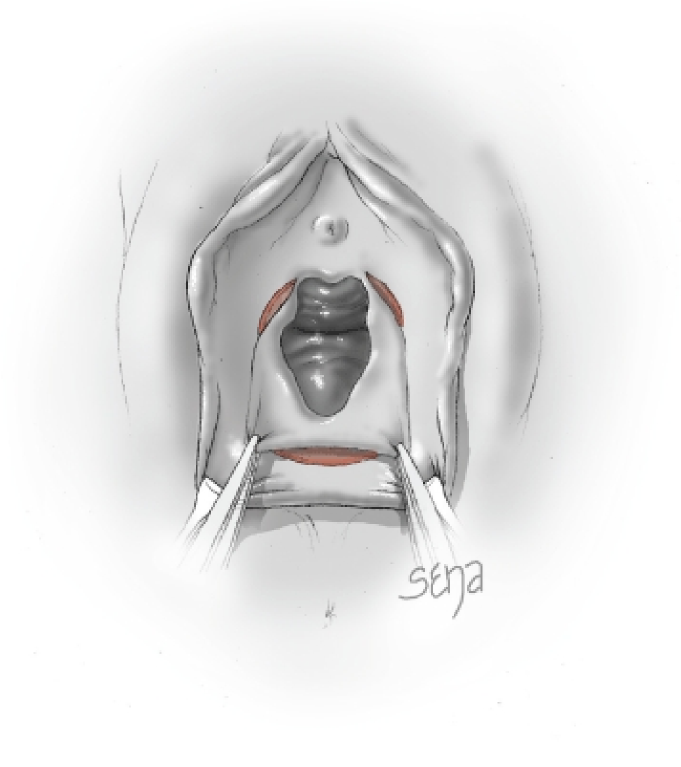
Surgical Steps

1. **Anesthesia and Patient Positioning.** Surgical marking of the sensitive areas to be excised precedes administration of anesthesia. In most cases, vestibulectomy is an outpatient procedure conducted using general or regional anesthesia. The patient is placed in dorsal lithotomy position, and the vulvovaginal area is surgically prepared.

2. **Surgical Excision.** The primary incision is made to a depth of 2 to 5 mm along the Hart line down to the perineum and proximal to the hymenal ring. The amount of tissue removed anteroposteriorly varies according to sensitivity mapping, but traditionally, it begins in the periurethral area and extends from the openings of the Skene ducts to the perineum. Accordingly, care should be taken to avoid injury to the urethra and alteration of the urethral angle.

3. **Vaginal Mucosal Advancement.** Following tissue excision, the cut edge of the vaginal mucosal edge is undermined 1 to 2 cm cephalad and then pulled distally to cover the defect (Fig. 41-9.2). To prevent hematoma and wound separation, hemostasis should be achieved prior to final suturing.

FIGURE 41-9.2



Source: Schorge JO, Schaffer JI, Halvorson LM, Hoffman BL, Bradshaw KD, Cunningham FG: *Williams Gynecology*: http://www.accessmedicine.com

Vaginal mucosal advancement.

4. **Wound Closure.** A deep closure layer using interrupted 3-0 delayed-absorbable sutures approximates the vaginal wall to its new site covering the vestibular defect. The superficial incision between the skin and vaginal epithelium is closed in an interrupted fashion with 4-0 delayed-absorbable suture.

Postoperative

Cool packs are used to relieve immediate discomfort, whereas sitz baths are initiated after the first 24 hours. Recovery typically is fast and without complications, and wound healing takes 4 to 8 weeks. Women usually meet with their surgeon during this time and are instructed to gradually resume intercourse 6 to 8 weeks following surgery (Bergeron, 2001).

41-10 LABIAL MINORA REDUCTION

When outstretched, most labia minora span 5 cm or less from their base to lateral edge. In some women, this span may be greater and may cause aesthetic dissatisfaction, discomfort with tight clothing, pain with exercise, and insertional dyspareunia. As a result, some elect to have their labia minora reduced surgically.

Goals of surgery include reduction in labial size and maintenance of normal vulvar anatomy. Early reductive procedures involved anteroposterior excision along the base of the labia and re-approximation of the surgical edges. Drawbacks to this approach include a marked color contrast at the suture line, where the dark outer labial minoral surface abutts the lighter inner surface. Moreover, the labial edge is often replaced by a stiff suture line. To reduce these affects, alternate techniques have incorporated labial wedging or Z- or W-plasty incisions (Alter, 1998; Giraldo, 2004; Maas, 2000).

Preoperative

CONSENT

Labial minora reductive surgery is a safe and effective means to remove excess labial tissues. As with any aesthetic procedure, women who are seeking cosmetic correction should have realistic expectations as to the final size, shape, and color of the labia. Wound complications such as hematoma, cellulitis, and incisional dehiscence are rare but should be discussed during counseling. Similarly, postoperative dyspareunia is uncommon but should be noted in the consenting process.

PATIENT PREPARATION

Antibiotics are not required for infection prevention, and no special preoperative patient preparation is needed.

Intraoperative

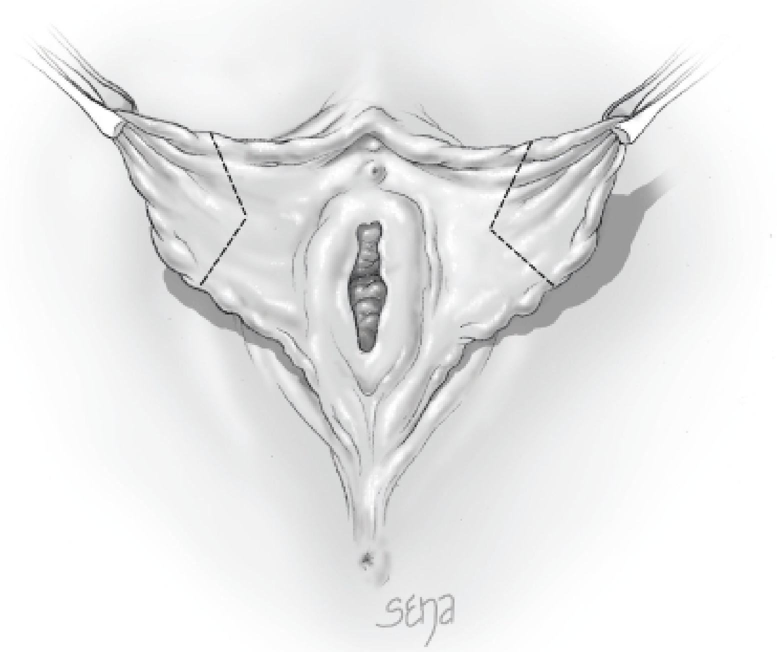
Surgical Steps

1. **Anesthesia and Patient Positioning.** Labial minora reduction may be performed as an outpatient procedure using general or regional anesthesia. After anesthesia has been delivered, the patient is placed in dorsal lithotomy position, and the vulva is surgically prepared.

2. **Labial Marking.** Excessive tissue removal should be avoided because aggressive reduction may lead to anteroposterior narrowing and discomfort during subsequent intercourse. For this reason, during surgical marking, the surgeon may chose to place several fingers in the vagina to distend its caliber. The labia minora then are outstretched laterally.

   The desired lateral span of the labia will vary among women, but most surgeons strive to create a span of 1 to 2 cm. Asymmetry between labia is common, and surgical marking helps to even this difference. With a surgical marker, the surgeon draws a V-shaped wedge on the ventral and dorsal surfaces of the labia minora demarcating the tissue for excision (Fig 41-10.1).

FIGURE 41-10.1



Source: Schorge JO, Schaffer JI, Halvorson LM, Hoffman BL, Bradshaw KD, Cunningham FG: *Williams Gynecology*: http://www.accessmedicine.com

Incision lines.

3. **Incision Infiltration.** The labia minora have a rich blood supply. To decrease bleeding, the incision may be infiltrated with a solution of 1-percent lidocaine and epinephrine in a 1:200,000 dilution.

4. **Wedge Excision.** The tissue wedge then is excised sharply. Hemostasis may be achieved using electrosurgical coagulation and is important in avoiding hematoma formation.

5. **Incision Closure.** The subcutaneous layers of the labia are re-approximated beginning proximally at the tip of the wedge. Interrupted sutures of 4-0 delayed-absorbable suture then are added outward toward the base to close the remainder of the wound. The skin is reapproximated with 5-0 delayed-absorbable suture in a running subcuticular or interrupted fashion.

Postoperative

Perineal hygiene is emphasized during the initial weeks following surgery. Exercise and intercourse may resume following wound healing.

41-11 TRANSVERSE VAGINAL SEPTUM EXCISION

Failure of the vaginal plate to regress completely during embryologic development can result in formation of transverse septums at various levels of the vagina (see Fig. 18-5). Some septums may have small perforations that allow prolonged menstrual blood

egress, whereas others may have no openings and lead to accumulations and distention in the upper reproductive tract. Some may be managed conservatively with observation, whereas those associated with pain, infertility, or hematometra require excision (see Chap. 18, Diagnosis and Treatment).

Preoperative

PATIENT SELECTION

Similar to the McIndoe procedure, this procedure is best performed in a mature adolescent or young adult rather than in children (see Section 41-12, McIndoe Procedure). First, production of estrogen following puberty can improve healing. Moreover, excision of these septums requires some degree of postoperative vaginal dilatation to avoid stricture, and regimen compliance may be limited in young girls. Unfortunately, not all cases can be delayed. Limitations include development of hematocolpos or hematometra. A fuller discussion of conservative management and surgical indications is found in Chapter 18, Diagnosis and Treatment.

CONSENT

Risks of transverse septum excision mirror those associated with the McIndoe procedure, except that skin grafting and its attendant risks usually are avoided unless the vaginal septum is long. Accordingly, vaginal stricture following excision is a significant risk. In their small series, Joki-ErkkilÃ¤ and Heinonen (2003) found that two of three adolescents required re-excision of scar tissue following initial septum removal.

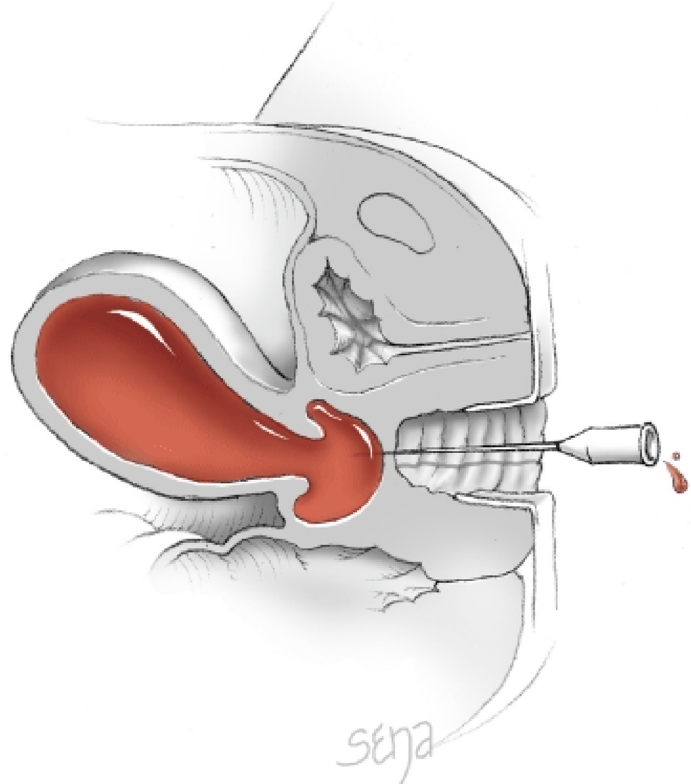
Intraoperative

Surgical Steps

1. **Anesthesia and Patient Positioning.** After administration of general anesthesia, a second-generation cephalosporin such as cefoxitin 2 g intravenously is given. The patient is placed in dorsal lithotomy position, and the perineum and vagina are surgically prepared. A Foley catheter serves as a guide to avoid urethral injury during septum excision.

2. **Incision.** Retractors are placed to reveal the upper extent of the vagina. With higher-level septums, diagnostic needle aspiration of the suspected hematocolpos can help to locate the upper vagina to determine the direction of dissection (Fig. 41-11.1). The vaginal vault is then incised transversely to avoid laceration of the urethra, bladder, or rectum (Fig. 41-11.2).

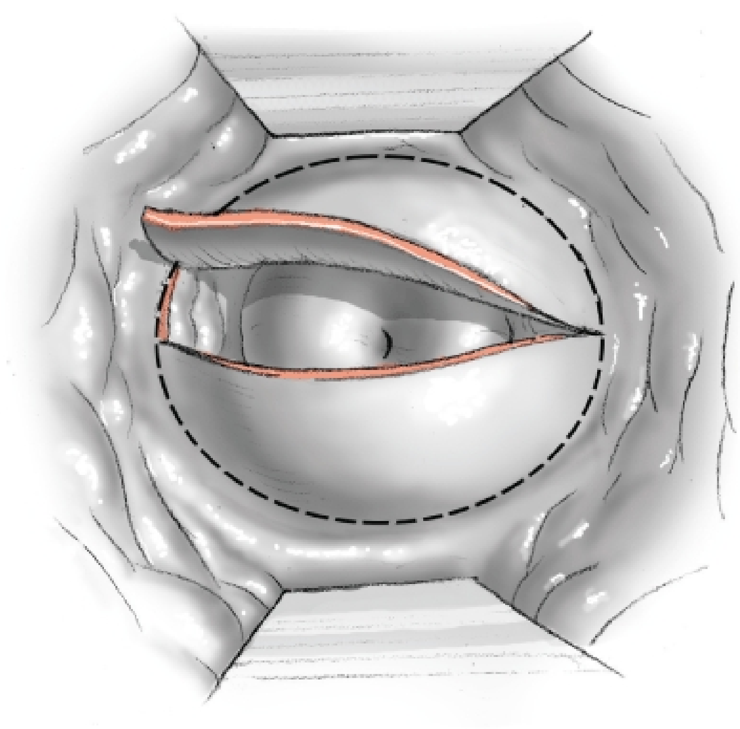
FIGURE 41-11.1



Source: Schorge JO, Schaffer JI, Halvorson LM, Hoffman BL, Bradshaw KD, Cunningham FG: *Williams Gynecology*: http://www.accessmedicine.com

Diagnostic needle aspiration to direct dissection.

FIGURE 41-11.2



Source: Schorge JO, Schaffer JI, Halvorson LM, Hoffman BL, Bradshaw KD, Cunningham FG: *Williams Gynecology*: http://www.accessmedicine.com

Septum incision.

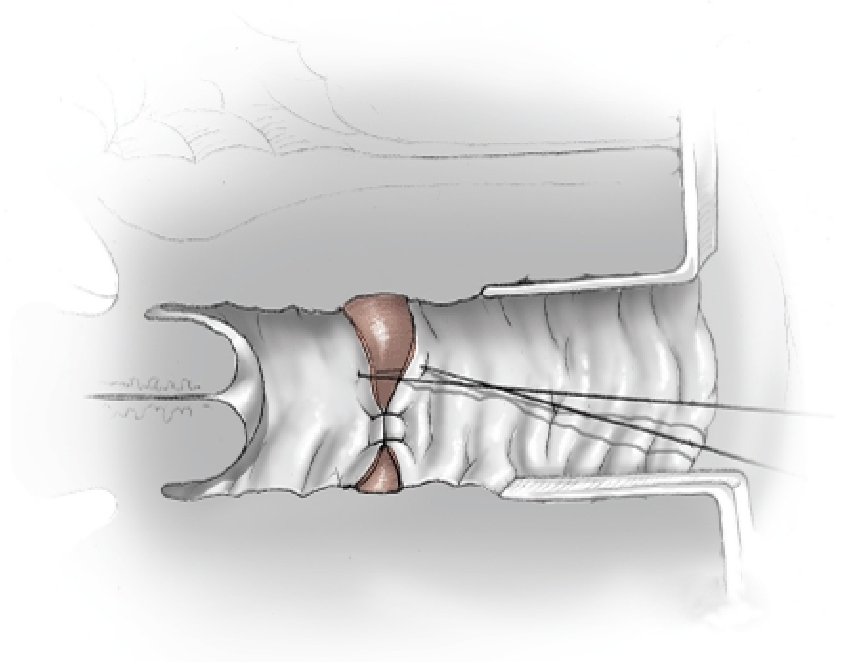
3. **Dissection.** Depending on its thickness, both blunt and sharp dissection may be required to transect the septum. Blunt probing of septal tissue to identify the upper vagina may be necessary to direct dissection. Similarly, the Foley catheter or a finger in the rectum may assist with orientation.

4. **Excision.** Once the septum is transected, the cervix is identified. The septum is excised widely to its base to minimize postoperative stricture.

5. **Wound Closure.** The vaginal mucosa is undermined, and the cephalad mucosal edge is sutured to the opposite caudad edge (Fig. 41-11.3). A circumferential ring of interrupted sutures thus is constructed using 2-0 delayed-absorbable suture. A soft stent, similar to that used in the McIndoe procedure, is placed into the vagina.

   If the vaginal septum is long and mucosal re-approximation is not possible, a skin graft can be taken and applied in a manner similar to the McIndoe procedure.

FIGURE 41-11.3



Source: Schorge JO, Schaffer JI, Halvorson LM, Hoffman BL, Bradshaw KD, Cunningham FG: *Williams Gynecology*: http://www.accessmedicine.com

Vaginal mucosa reapproximation.

Postoperative

The Foley catheter may be removed on the first postoperative day. The remaining postoperative care mirrors that for the McIndoe procedure.

41-12 MCINDOE PROCEDURE

Creation of a functional vagina is the treatment goal for many women with congenital agenesis of the vagina. Although several surgical and nonsurgical approaches have been used, the McIndoe procedure is employed most commonly in the United States (see Chap. 18, Treatment). With this technique, a canal is formed between the urethra and urinary bladder anteriorly and the rectum posteriorly (McIndoe, 1938). A skin graft obtained from the patient's buttock, thigh, or inguinal regional then is wrapped around a soft mold and placed into the newly created vagina to allow epithelialization. Alternatively, other materials have been used to line the neovagina. These include amnionic membrane, cutaneous and myocutaneous flaps, buccal mucosa, and Interceed absorbable adhesion barrier (Ethicon, Somerville, NJ) (Ashworth, 1986; Lin, 2003; McCraw, 1976; Motoyama, 2003).

Preoperative

PATIENT SELECTION

Vaginal stricture can be a significant complication following the McIndoe procedure (Alessandrescu, 1996). Thus, adherence to a postoperative regimen of vaginal dilatation is mandatory. For this reason, surgery may be postponed until a patient has reached a level of maturity to comply (American College of Obstetricians and Gynecologists, 2002).

CONSENT

Prior to surgery, patients should be informed of overall success rates with this procedure. In a Mayo Clinic series of 225 patients, the McIndoe procedure provided a functional vagina to afford "satisfactory" intercourse in 85 percent of patients. In this review, the

cumulative complication rate was 10 percent and included vaginal stricture, pelvic organ prolapse, graft failure, postcoital bleeding, and fistulas involving either the bladder or rectum (Klingele, 2003). Additionally, complications at the skin graft harvest site involved cheloid formation, wound infection, and postoperative dysaesthesias.

PATIENT PREPARATION

Intravenous administration of a second-generation cephalosporin such as cefoxitin 2 g in a single preoperative dose is recommended. Bowel preparation is completed the evening prior to surgery (see Chap. 39, Gastrointestinal Bowel Preparation).

Intraoperative

INSTRUMENTS

Electrodermatome

The skin grafts used to line the neovagina are harvested from a donor site with the aid of an electrodermatome, which is able to shave grafts of varying size and depth. Both split- and full-thickness skin grafts have been used in the McIndoe procedure, and the electrodermatome settings are adjusted to shave the desired depth.

Vaginal Mold

Following graft harvesting and neovagina formation, a stent is needed to apply the graft to the vaginal walls and hold it in place. Both soft and rigid forms have been used. Rigid mold materials have included balsa wood, pyrex, plastic, and synthetic silicone-based materials (McIndoe, 1938; Ozek, 1999; Seccia, 2002; Yu, 2004). Unfortunately, rigid and semirigid stents have led to graft loss, fibrosis, contracture, and pressure-related bladder or rectal fistulas.

Use of soft stents has decreased the number of these complications. Inflatable rubber stents or condoms filled with foam rubber or other soft, compressible materials are examples (Adamson, 2004; Barutcu, 1998; Concannon, 1993). The vaginal graft produces abundant exudates, and poor drainage may lead to graft maceration, sloughing, and detachment. Accordingly, suction is attached to the soft stents to aid drainage of the neovagina (Yu, 2004).

Surgical Steps

1. **Anesthesia and Patient Positioning.** General anesthesia is administered, and the patient initially is positioned prone for skin graft harvesting from the buttock. Alternatively, skin may be obtained from the thigh, hip, or inguinal area. Goals of harvesting are to choose a location that has minimal hair growth and is cosmetically discreet. The assistance of a plastic surgeon may be enlisted for skin graft procurement.

2. **Skin Graft.** The surgeon first marks the outline of the wound on the skin of the donor site, enlarging it by 3 to 5 percent to allow for skin shrinkage immediately after excision. The surgeon uses the electrodermatome to remove a single strip of skin that is typically 0.018 in thick, 8 to 9 cm wide, and 18 to 20 cm long (Fig. 41-12.1). Alternatively, two smaller strips of 5 cm by 10 cm can be obtained from each buttock.

   Following excision, the graft is placed in a pan of sterile saline. The harvest sites on the buttocks are dressed with a Tegaderm dressing (3M, St. Paul, MN).

FIGURE 41-12.1

Source: Schorge JO, Schaffer JI, Halvorson LM, Hoffman BL, Bradshaw KD, Cunningham FG: *Williams Gynecology*: http://www.accessmedicine.com

Skin graft harvest.

3. **Perineal Incision.** The patient then is placed in dorsal lithotomy position, perineal cleansing is performed, and a Foley catheter is placed.

   The lower edge of each labia minora is grasped with Allis clamps and extended laterally. A third Allis clamp is placed on the vestibular skin below the urethra and is lifted superiorly. A dimple in the vestibule typically is identified below the urethra. A 2- to 3-cm transverse incision is made sharply across it. Allis clamps then are placed on the inferior and superior edges of this incision and retracted.

4. **Neovaginal Dissection.** In creation of the new vagina, the goal is to create a canal that is bounded anteriorly by the fascia that supports the urethra and bladder. Posterior limits involve the perirectal fascia and rectum, and lateral borders are the pubococcygeus muscles. Each canal is created to reach a depth of approximately 12 cm, but entering the cul-de-sac of Douglas peritoneum should be avoided.

   Initially, two canals are created on either side of the median raphe. The raphe is a midline collection of dense connective tissue bands that stretch between the urethra and bladder above and the rectum below (Fig. 41-12.2). These canals are formed initially using a spreading motion with blunt-tipped scissors. Fingers then are insinuated into the forming canals. Pressure is exerted cephalad to extend the canal depth. Additionally, the finger pads are rolled outward, and lateral pressure is applied to widen the canal. Posterior pressure should be avoided to prevent entering the rectum.

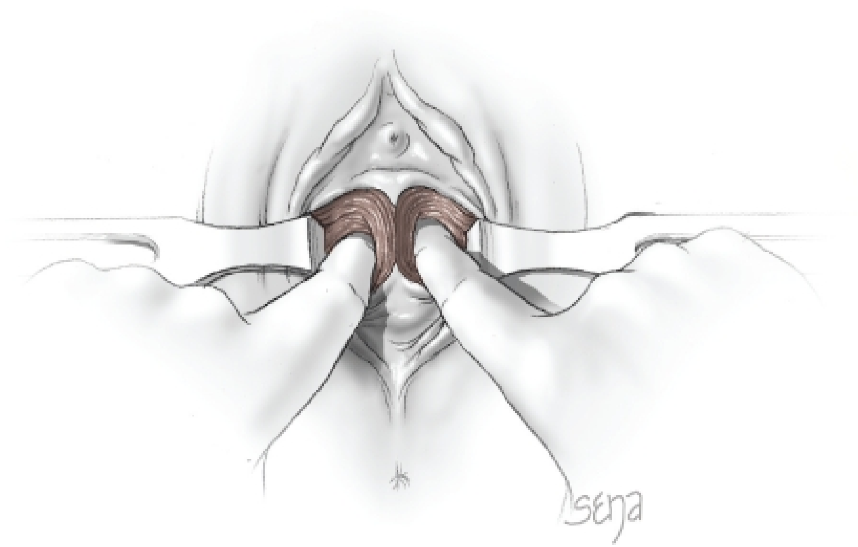
   During dissection, several points are noteworthy. First, with initial distal dissection, the surgeon may meet greater resistance than with the tissues more cephalad. Secondly, remaining in the correct dissection plane can be difficult. Accordingly, during dissection, a finger may be placed by the surgeon into the rectum to identify its location and avert perforation. Similarly, the Foley catheter may serve as an orientation tool anteriorly.

   To expand the space, retractors can be placed along the lateral walls of the forming canals and stretched outward. Moreover, incising the medial fibers of the pubococcygeus muscles can add width. These muscles are cut along the lateral aspect of each canal and at a level midway along the length of the canals.

   Cephalad, the canal is extended to within 2 cm of the cul-de-sac of Douglas. This leaves a beneficial layer of connective

tissue affixed to the peritoneum. First, the skin graft will attach more effectively to this connective tissue than to a smooth peritoneal surface. Second, rates of subsequent enterocoele formation are lowered.

FIGURE 41-12.2



Source: Schorge JO, Schaffer JI, Halvorson LM, Hoffman BL, Bradshaw KD, Cunningham FG: *Williams Gynecology*: http://www.accessmedicine.com

Neovaginal dissection.

5. **Cutting the Median Raphe.** On completion of the two smaller canals, the median raphe is cut. The final single canal measures approximately 10 to 12 cm deep and three fingerbreadths wide.

6. **Hemostasis.** Following surgery, collections of blood can separate the mold from the canal bed. Thus, hemostasis is required prior to mold insertion.

7. **Mold Preparation.** Attention then is directed to covering the vaginal mold with the harvested skin. The graft is removed from the saline bath. One end of the graft is placed at the base of the mold with the external surface of the skin facing the mold. The long axis of the graft is laid parallel to the long axis of the mold. The graft then is draped up and over the mold tip (Fig. 41-12.3).

   The lateral edges of the skin graft then are approximated on either side of the mold using interrupted suture of 3-0 catgut.

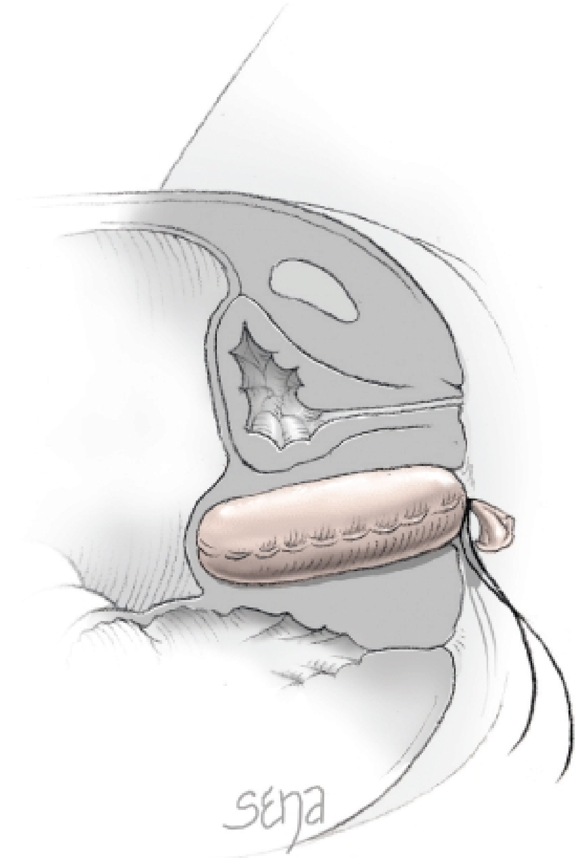
FIGURE 41-12.3

Source: Schorge JO, Schaffer JI, Halvorson LM, Hoffman BL, Bradshaw KD, Cunningham FG: *Williams Gynecology*: http://www.accessmedicine.com

Skin graft placed around soft mold.

8. **Mold Customizing.** Customizing the mold to the size of the created neovaginal canal is essential. If a mold width is too large, it can cause pressure necrosis or inhibit adequate drainage, which, as noted earlier, can lead to tissue maceration. Moreover, at the time of postoperative mold removal, a mold that is too large and snuggly fitted into the neovagina may pull the graft loose. Once the mold is sized and constructed appropriately, it is inserted (Fig. 41-12.4).

FIGURE 41-12.4



Source: Schorge JO, Schaffer JI, Halvorson LM, Hoffman BL, Bradshaw KD, Cunningham FG: *Williams Gynecology*: http://www.accessmedicine.com

Skin graft and mold in place.

9. **Perineal Sutures.** The edges of the skin graft at the distal end of the mold then are re-approximated circumferentially to the distal opening of the neovagina using 4-0 or 5-0 delayed-absorbable suture.

   The labia minora, if sufficiently long, can be sutured together along the midline with 2-0 silk sutures to help hold the mold in place for the first 7 postoperative days. An elastic compression dressing is placed on the perineum.

Postoperative

The soft mold and Foley catheter are left in place for 7 days following surgery. To minimize dislodgement of the mold and wound contamination, a low-residue diet and loperamide 2 mg bid orally is used to limit defecation.

At the time of mold removal, an operating room, general anesthesia, and dorsal lithotomy position are employed. Stitches in the labia minora are cut, and the mold is removed. To lessen the risk of graft avulsion, irrigation is used to reduce adherence between graft and mold.

Several schedules for postoperative dilatation have been described. Commonly, the size of the mold placed at surgery is too large for maintenance use. Therefore, a smaller mold may be used initially and then gradually replaced with larger ones as the vagina stretches. For the first 6 weeks following surgery, the dilator is worn continuously except during defecation. During the subsequent 6 weeks, it is used only at night. Following these initial 3 months, patients then are instructed to either wear the dilator at night or engage in intercourse twice each week.

41-13 TREATMENT OF ECTOCERVICAL PREINVASIVE LESIONS

Cervical Cryotherapy

Cryotherapy has been used for decades to safely and effectively eliminate cervical intraepithelial lesions. This tool uses compressed gas to create extremely cold temperatures, which necrose cervical epithelium. In theory, as compressed gas expands, it draws heat away from its surroundings, in this case from the cervical epithelium.

An interfacing tip made of silver or copper, called the *cryoprobe,* allows contact and conduction of extreme cold across the surface of the cervix. When nitrous oxide gas is used, probe temperatures can reach â€“65Â°C, and cell death occurs at â€“20Â°C (Ferris, 1994; Gage, 1979).

As the cervical epithelium is cooled, an expanding layer of ice, called the *iceball,* forms beneath the center of the cryoprobe and grows circumferentially outward and past the margins of the probe. The portion of the iceball in which temperatures fall below â€“20Â°C is termed the *lethal zone.* This zone extends from the center of the cryoprobe to a point 2 mm inside the outer iceball edge. Outside this 2-mm point, tissue temperatures are warmer, and necrosis may be incomplete.

The expanding iceball grows in depth as well as circumference during treatment. Although this dimension cannot be seen, iceball depth is estimated to equal the lateral spread of the iceball away from the cryoprobe margin. To treat the endocervical glandular crypt involvement of most lesions, a depth of 5 mm is sufficient (Anderson, 1980; Boonstra, 1990a). For this reason, when cryotherapy is performed, the iceball is allowed to enlarge until reaching a mark 7 mm distal to the probe margin. This will ensure creation of a freezing depth of 7 mmâ€”a 5-mm lethal zone and a 2-mm zone of indeterminant tissue death (Ferris, 1994).

Many surgeons use a double-freeze method for cryotherapy in which time rather than iceball dimensions define the process. Refrigerant gas is delivered for 3 minutes to create the iceball. After this, the iceball is allowed to thaw for 5 minutes, at which point a second 3-minute freeze is performed (Creasman, 1984). Studies show that a single freezing period should be avoided because of associated high rates of dysplasia recurrence in the first year following treatment (Creasman, 1984; Schantz, 1984).

The specific indications and long-term rates of success for cryotherapy are discussed in Chapter 29, Cryosurgery. In general, cryotherapy is appropriate for squamous cervical intraepithelial lesions that do not extend deeper than 5 mm into the endocervical canal, do not span more than two quadrants of the ectocervix, and are not associated with unsatisfactory colposcopic examination or abnormal glandular cytology.

Preoperative

PATIENT EVALUATION

In the United States, women receive colposcopic evaluation and histologic interpretation of cervical biopsies prior to cryotherapy. Recently, a "see and treat" approach has been discussed in which immediate treatment rather than biopsy is initiated during colposcopy for abnormal cervical cytology (Dainty, 2005; Numnum, 2005). However, this type of approach, particularly in low-resource settings, is most successful when linked with excisional and not ablative procedures.

CONSENT

Although cryotherapy complications are uncommon, women should be counseled on expected postoperative changes and surgical risks. Watery vaginal discharge and vaginal spotting both may persist for several weeks following treatment. Fortunately, severe hemorrhage is rare (Denny, 2005). Abdominal cramping is common but typically subsides within the first 24 hours. Infrequently, women may experience a vasovagal reaction during treatment, and care should be supportive.

Surgical consents include both short- and long-term effects and typically describe risks for cervical stenosis, pelvic inflammatory disease (PID), and treatment failure. Rates for stenosis and PID are very low, and treatment failures for cervical intraepithelial neoplasia (CIN) I and II have been cited at 6 to 10 percent (Benedet, 1981, 1987; Jacob, 2005; Ostergard, 1980). In addition, Jobson and Homesley (1984) reported retraction of the squamocolumnar junction into the endocervical canal in patients following cryotherapy. In their study, postoperative surveillance revealed that this retraction resulted in a 47-percent rate of subsequent inadequate colposcopic examination, which often required more invasive evaluation. Infertility and pregnancy complications have not been associated with this treatment modality (Weed, 1978).

PATIENT PREPARATION

Ideally, cryotherapy is performed after completion of menstruation. This decreases the chances of pregnancy and allows cervical healing prior to the next menses. If it is performed prior to menses, postoperative swelling can block menstrual flow and intensify cramping. Before cryosurgery, a normal bimanual examination should be confirmed. If there is a possibility of pregnancy, β-hCG level testing should precede treatment.

Intraoperative

INSTRUMENTS

Cryotherapy typically requires a tank of refrigerant gas plus a cryogun, connecting tubing, pressure gauge, and cryoprobe. Nitrous oxide is the most commonly used refrigerant gas, although carbon dioxide also has been employed. A 20-lb tank is sufficiently large to deliver gas under the necessary 20 lb of pressure needed to cool tissues adequately. In contrast, smaller tanks may fail to generate sustained pressures and may hinder formation of a sufficiently large iceball. Gas moves through connecting tubing into the barrel of the cryogun and then to the cryoprobe tip. Circumferential grooves within the cryoprobe stem allow it to be attached securely into position at the end of the cryogun.

Selection of an appropriate probe is individualized but should cover the transformation zone and lesion. For this reason, cryoprobes come in different sizes and shapes (Fig. 41-13.1). For example, flat-faced probes are used for lesions located on the cervical portio. Advantageously, this shape has a lower tendency to push the resulting squamocolumnar junction toward the endocervical canal. This decreases the risk of unsatisfactory colposcopic examination following treatment (Stienstra, 1999). Use of smaller (19 mm) flat probes, however, has been discouraged following studies that indicated insufficient lethal zones and tissue destruction (Boonstra, 1990b; Ferris, 1994). Cone-shaped probes and those with nipple-shaped tips allow extension of the iceball into the endocervical canal. To minimize cervical stenosis, however, such nipple tips should not measure longer than 5 mm.

FIGURE 41-13.1

Source: Schorge JO, Schaffer JI, Halvorson LM, Hoffman BL, Bradshaw KD, Cunningham FG: *Williams Gynecology*: http://www.accessmedicine.com

Cryomachine and variety of cryoprobes tips. (Courtesy of CooperSurgical.)

Prior to treatment, the gas tank valve is opened, and the pressure gauge should indicate delivery of 20 lb of pressure. The cryogun trigger is squeezed to confirm that the cryoprobe cools adequately and that no excess gas escapes at the junction of cryogun and cryoprobe. Soft hissing is expected, but loud hissing and gas escape indicate that the loud rubber O-ring found between these two pieces should be replaced.

Surgical Steps

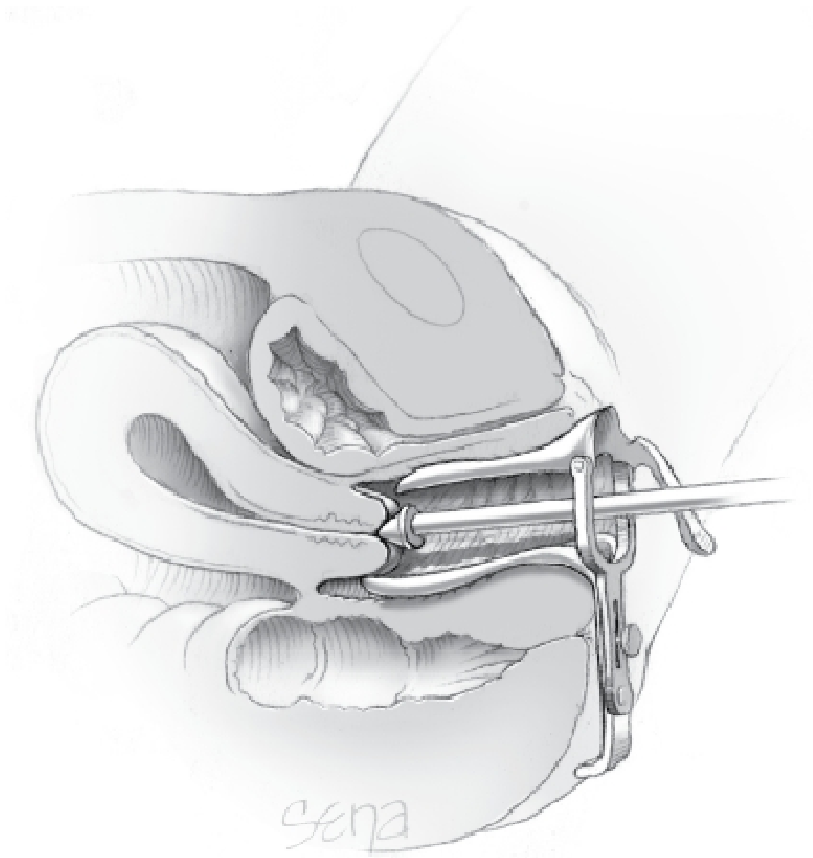
1. **Analgesia and Patient Positioning.** Cryotherapy may be performed in an office setting and requires no significant analgesia. However, to help attenuate associated uterine cramping, women commonly are given a nonsteroidal anti-inflammatory drug (NSAID) such as naproxyn sodium 550 mg orally 30 to 60 minutes prior to therapy. Although not used routinely, paracervical block and cervical subepithelial injection of 1-percent lidocaine have been associated with decreased pain scores (Harper, 1997, 1998).

   The patient is positioned in the dorsal lithotomy position, and a speculum is placed. No vaginal cleansing prep is required. The appropriate-sized cryoprobe is attached onto the end of the cryogun barrel. A water-based lubricant jelly is smeared on the end of the cryoprobe to ensure even tissue contact.

2. **Cryoprobe Placement.** The probe then is pressed firmly against the cervix (Fig. 41-13.2). The cryogun trigger is squeezed, a light hissing sound typically is heard, and frost begins to cover the probe.

   The cryoprobe should not contact the vaginal sidewalls. If this is identified, gas delivery is stopped to allow probe warming. The probe then is gently teased away from the wall, after which the procedure is continued.

FIGURE 41-13.2



Source: Schorge JO, Schaffer JI, Halvorson LM, Hoffman BL, Bradshaw KD, Cunningham FG: *Williams Gynecology*: http://www.accessmedicine.com

Cryoprobe placement.

3. **Iceball Formation.** The trigger is held until the iceball extends 7 mm distal to the outer margin of the cryoprobe (Fig 41-13.3). Freezing typically requires 3 minutes. During the freezing process, ice may form that blocks the gas tubing. For this reason, many manufacturers recommend pushing the defrost button for less than 1 second every 20 seconds during freezing.

Photographs of cryotherapy. **A.** Cryotip applied to cervix. **B.** Creation of advancing iceball. (Courtesy of Dr. Claudia Werner.)

4. **First Thaw.** At this point, the trigger is released. The probe quickly warms and can be removed from the cervix. Attempts to remove the probe prior to its complete defrosting can cause patient discomfort and bleeding. The surface of the cervix is allowed to thaw during the following 5 minutes.

5. **Second Cycle.** Subsequently, the freezing cycle is repeated for an additional 3 minutes. At completion of the second cycle, the cryoprobe and then the speculum are removed. Because vasovagal responses can be seen with this procedure, patients are assisted to a sitting position slowly.

Postoperative

Copious watery vaginal discharge that develops after treatment usually requires sanitary pad use, and tampons are discouraged. Although some advocate dÃ©bridement of the necrotic eschar to decrease the amount of discharge, Harper and colleagues (2000) reported no affect in the amount or duration of this discharge with such dÃ©bridement. Vaginal spotting is expected and can persist for weeks, but hemorrhage is rare. During the first few days following cryotherapy, patients may complain of diffuse mild lower abdominal pain or cramping, for which NSAIDs typically provide relief. Infrequently, severe pain and cramping may result from necrotic tissue obstructing the endocervical canal and is termed *necrotic plug syndrome.* Removal of the obstructing tissue typically resolves symptoms.

Because a large area of the cervix is denuded after cryotherapy, there is an increased potential for infection. Accordingly, patients should abstain from intercourse during the 4 weeks following surgery. If abstinence is not feasible, then condom use is encouraged.

Depending on patient symptoms, work and exercise may resume following treatment.

Loop Electrosurgical Excision Procedure

Loop electrosurgical excision procedure (LEEP), also known as *large loop excision of the transformation zone* (LLETZ), uses electric current to generate energy waveforms through a metal electrode that either cuts or desiccates cervical tissues. These thin wire semicircular electrodes allow clinicians to excise cervical lesions in an office setting with minimal patient discomfort, cost, and complications. In addition, LEEP permits submission of a surgical specimen for additional evaluation. In the United States, electrosurgical treatment of CIN is popular and often preferred over cryotherapy or laser ablation (see Chap. 29, Loop Electrosurgical Excision Procedure).

Preoperative

PATIENT EVALUATION

As with cryotherapy and laser ablation, women in the United States undergo colposcopy and histologic review of colposcopic biopsies prior to LEEP. Preoperative patient preparation mirrors that for cryotherapy (Patient Preparation).

CONSENT

This procedure is associated with low morbidity, and overall complication rates approximate 10 percent (Dunn, 2004). Major complications are rare (0.5 percent) and may include bowel or bladder injury and hemorrhage (Dunn, 2003; Kurata, 2003). Short-term complications such as abdominal pain, vaginal bleeding, vaginal discharge, and bladder spasm may be treated symptomatically.

Long-term complications include failure to treat the cervical lesion completely and cervical stenosis. Persistent disease typically is noted in initial surveillance PAP smear testing following LEEP (see Chap. 29, Further Cytologic and Colposcopic Surveillance). However, such treatment failure rates are low (approximately 5 percent) and are positively correlated with initial excised lesion size (Alvarez, 1994; Gunasekera, 1990; Mitchell, 1998). Cervical stenosis is estimated to complicate less than 6 percent of cases, and risk factors include the presence of an endocervical lesion and excision of a large tissue volume (Baldauf, 1996; Suh-Burgmann, 2000).

The effects of LEEP and obstetric outcomes are unclear. Several studies have shown that pregnancy does not appear to be adversely affected by LEEP, whereas meta-analysis reviews by others have noted increased risks of premature labor and premature rupture of the membranes (Crane, 2003; Cruickshank, 1995; Ferenczy, 1995; Kyrgiou, 2006; Tan, 2004a).

Intraoperative

INSTRUMENTS

Tissue excision during LEEP requires an electrosurgical unit, wire loop electrodes, insulated speculum, and smoke evacuation system. Electrosurgical units used in LEEP procedures generate high-frequency (350 to 1200 kHz), low-voltage (200 to 500 V) electric current. Because of the risk for electrical burns to the patient from stray current, grounding pads should contact patients on conductive tissue that is close to the operative site (see Chap. 40, Patient Grounding).

Similarly, an insulated speculum is used in LEEP procedures to limit the risk of stray current conductance to the patient. The insulated speculum should have a port for smoke evacuation tubing, which assists in clearing smoke from the operating field to improve visualization.

Surgical smoke plumes have contents including carbon monoxide, polyaromatic hydrocarbons, and a variety of trace toxic gases (National Institute for Occupational Safety and Health, 1999). Although there has been no documented transmission of infectious disease through surgical smoke, the potential for generating infectious viral fragments may exist. For these reasons, local smoke evacuation systems are recommended.

Electric current is directed to tissue via a 0.2-mm stainless steel or tungsten wire electrode that comes in a variety of sizes customized to treat lesions of various sizes (Fig. 41-13.4). These instruments are disposable and are discarded after each patient procedure.

FIGURE 41-13.4

Source: Schorge JO, Schaffer JI, Halvorson LM, Hoffman BL, Bradshaw KD, Cunningham FG: *Williams Gynecology*: http://www.accessmedicine.com

Variety of loop electrosurgical excision procedure (LEEP) electrodes. (Courtesy of Utah Medical Products, Inc.)

Surgical Steps

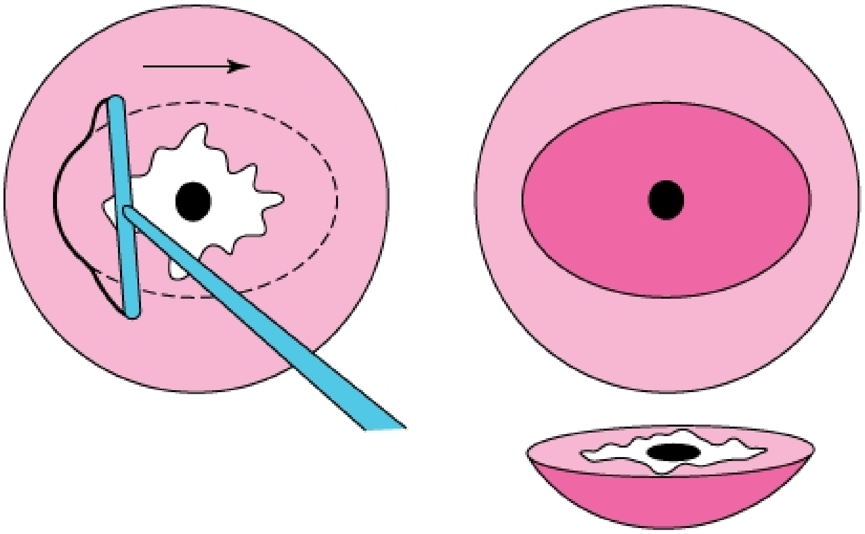
1. **Anesthesia and Patient Positioning.** The patient is placed in the dorsal lithotomy position, and the electrosurgical grounding pad is placed on the upper thigh or buttock. The insulated speculum is inserted into the vagina, and smoke evacuation tubing is attached. The application of Lugol solution outlines lesion margins before starting the procedure (see Chap. 29, Lugol Solution). For most patients, LEEP is an office procedure, typically performed under local analgesia. Vasoconstricting solutions of either pitressin and 1-percent lidocaine solution (10 units pitressin in 30 mL of lidocaine) or 1-percent lidocaine and epinephrine (1:100,000 dilution) may be used. A 25- to 27-gauge needle is used to circumferentially inject 5 to 10 mL of either solution 1 to 2 cm deep into the cervix outside the area to be excised. Cervical blanching should be seen.

2. **Single-Pass Excision.** Ideally, the lesion should be excised in one pass, and the appropriately sized loop is selected for this goal. If colposcopy is satisfactory, the correct loop diameter should incorporate the entire lesion diameter to a depth of 5 to 8 mm. The electrosurgical unit is set to cutting mode, and typically 30 to 50 W is used depending on loop size. Larger loops require higher wattage.

   To excise the lesion, a loop is positioned 3 to 5 mm outside the lateral perimeter of the lesion (Fig. 41-13.5). Current through the loop is activated prior to tissue contact, during which electric sparks at the loop tip may be seen. The loop is introduced to the cervix at a right angle to its surface. The loop is drawn parallel to the surface until a point 3 to 5 mm outside the opposite border of the lesion is reached. The loop then is withdrawn slowly, positioning it at right angles to the surface. Current is stopped as soon as the loop exits the tissue.

Following excision, the specimen is placed in formalin for pathologic evaluation.

FIGURE 41-13.5

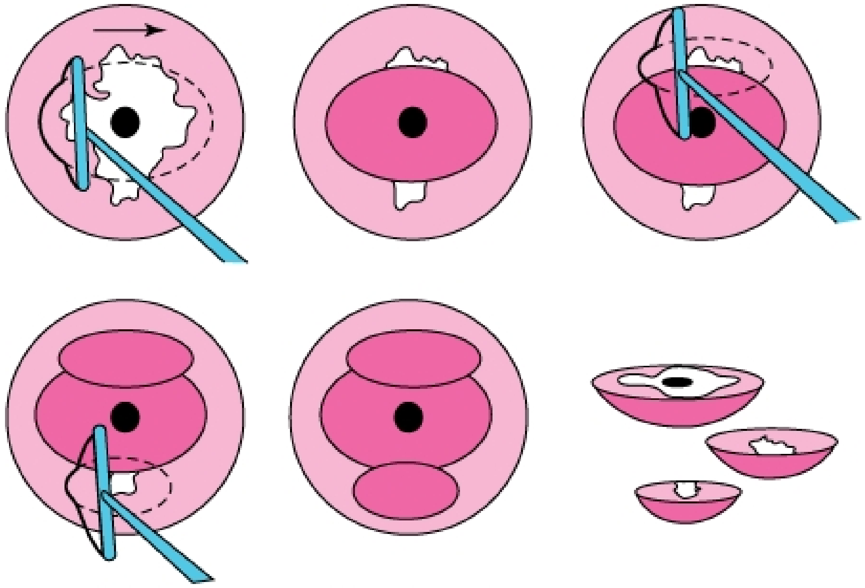


Source: Schorge JO, Schaffer JI, Halvorson LM, Hoffman BL, Bradshaw KD, Cunningham FG: *Williams Gynecology*: http://www.accessmedicine.com

Single-pass excision procedure.

3. **Multiple-Pass Excision.** Less commonly, bulky lesions may require multiple passes using a combination of loop electrode sizes (Fig. 41-13.6).

FIGURE 41-13.6



Multiple-pass excision procedure.

4. **Control of Bleeding Sites.** Despite use of vasoconstrictors, bleeding following LEEP is common. Sites of active bleeding may be controlled using a 3- or 5-mm ball electrode and the electrosurgical unit switched to coagulation mode. Alternatively, Monsel solution can be applied with direct pressure to bleeding sites.

Postoperative

Following excision, patients typically will experience light spotting and cramping. Postoperative healing and patient care in general follow those for cryotherapy (Postoperative).

Carbon Dioxide Cervical Laser Ablation

The carbon dioxide (CO_2) laser produces a beam of infrared light with a wavelength of 10.6 μm. At its focal point, the laser energy produces heat sufficient to boil intracellular water and vaporize tissue.

Indications and success rates are discussed more fully in Chapter 29, Carbon Dioxide Laser. In general, laser ablation may be used in patients in whom the entire transformation zone can be seen during satisfactory colposcopy. There should be no evidence of microinvasive, invasive, or glandular disease, and cytology and histology should correlate positively (Martin-Hirsch, 2000).

Although research has shown laser ablation to be an effective tool in treating CIN, its popularity is decreasing. Laser units are significantly more expensive than those used for cryotherapy and LEEP. In addition, lesions are destroyed with ablation, and unlike LEEP, the opportunity for additional pathologic evaluation of surgical margins is lost. Finally, physician and staff training and certification typically are required for safe, effective use of laser equipment.

Preoperative

CONSENT

Laser ablation is considered a safe and effective means to treat CIN. As with any treatment of cervical dysplasia, patients should be counseled on the risks of disease persistence and recurrence following treatment. These risks and surgical complications are low and comparable with those of LEEP (Alvarez, 1994; Nuovo, 2000).

Intraoperative

INSTRUMENTS

Carbon dioxide laser machines suitable for cervical ablation are mobile, self-contained units. Tissue effects vary depending on the interval at which energy bursts are released. As a result, continuous waves (cutting) or pulsed energy (coagulation) can be released.

Because laser light is reflective, protective eye wear is required for all participants, and a sign is posted on the suite door warning that a laser procedure is in progress. For this same reason, a matte-surface speculum is necessary. As with LEEP, noxious smoke is generated, and a smoke evacuation system is recommended.

Surgical Steps

1. **Anesthesia and Patient Positioning.** Laser ablation for many women is an outpatient procedure performed in either an operating suite or an office depending on laser equipment location. In most cases, local analgesia combined with a vasoconstrictor is sufficient, and administration mirrors that used for LEEP (Surgical Steps). The patient is placed in the dorsal lithotomy position. A matte-surfaced speculum is inserted, and smoke evacuation tubing is attached to a port on the speculum. Misdirected laser energy can burn surrounding tissues and ignite paper drapes. Therefore, moistened cloth towels are draped outside the vulva to absorb errant energy. To delineate the area of excision, Lugol solution is applied.

2. **Laser Settings.** The colposcope-laser assembly is brought into position and focused on the ectocervix. The laser is set to achieve a power density (PD) of 600 to 1200 W/cm^2 in a continuous-wave mode.

3. **Ablation.** Initially, four dots are ablated at 12, 3, 6, and 9 o'clock positions on the perimeter of the ectocervix to surround the entire lesion. These dots serve as landmarks and are connected in an arching pattern to create a circle. Once encircled, the area is ablated to a depth of 5 to 7 mm (Fig. 41-13.7).

FIGURE 41-13.7

Source: Schorge JO, Schaffer JI, Halvorson LM, Hoffman BL, Bradshaw KD, Cunningham FG: *Williams Gynecology*: http://www.accessmedicine.com

Cervical bed following laser ablation. (Courtesy of Dr. Eddie McCord.)

4. **Endocervical Eversion.** To help prevent postoperative retraction of the squamocolumnar junction cephalad into the endocervical canal, the tissue immediately surrounding the endocervix is ablated less deeply. This allows the endocervical lining to evert.

5. **Hemostasis.** During ablation, bleeding is common. A defocused laser beam and a lower power setting in a super-pulse-wave mode will coagulate vessels and aid hemostasis. At the end of surgery, bleeding also may be controlled with an application of Monsel solution.

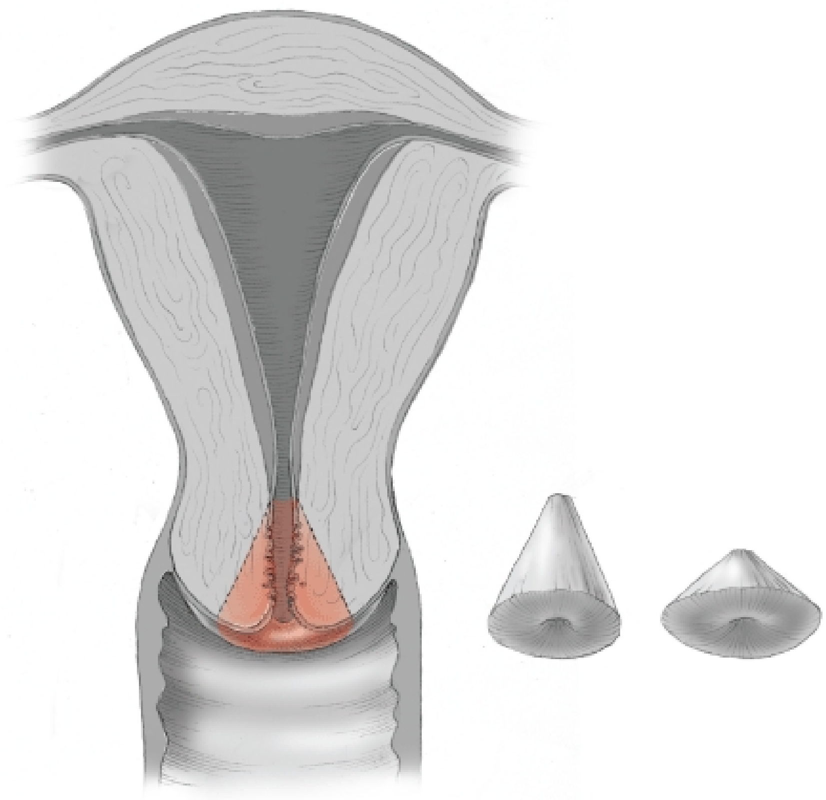
Postoperative

Cramping is common following surgery, and light bleeding may persist for a week. Postoperative patient counseling is similar to that for LEEP.

41-14 CERVICAL CONIZATION

Cervical conization removes ectocervical lesions and a portion of the endocervical canal by means of a cone-shaped tissue biopsy (Fig. 41-14.1). It is a safe, effective means to treat cervical intraepithelial neoplasia (CIN), carcinoma in situ (CIS), and adenocarcinoma in situ (AIS). Moreover, cervical conization is the standard treatment for women with unsatisfactory colposcopy, positive endocervical curettage, and discordant cytology and histology. Excision may be completed via scalpel, termed *cold-knife conization.* Alternatively, laser or loop electrosurgical excision procedure (LEEP) conization may be performed. Success rates for these excisional methods in the treatment of CIN have been found equivalent. However, LEEP conization has gained in popularity because of its ease of use and cost-effectiveness (Martin-Hirsch, 2000; Mitchell, 1998). Indications for and differences among these modalities are discussed in Chapter 29, Excisional Treatment Modalities.

FIGURE 41-14.1



Source: Schorge JO, Schaffer JI, Halvorson LM, Hoffman BL, Bradshaw KD, Cunningham FG: *Williams Gynecology*: http://www.accessmedicine.com

Cone-shaped tissue biopsies.

Preoperative

PATIENT EVALUATION

Prior to conization, women will have undergone colposcopic examination and histologic evaluation of biopsies. Beta human chorionic gonadotropin (β-hCG) testing is warranted prior to conization if pregnancy is suspected. If pregnancy is confirmed and invasion is not suspected colposcopically, postpartum management is reasonable. Conization during pregnancy has great morbidity because of increased vascularity and bleeding.

CONSENT

Risks associated with conization mirror those for LEEP excision of ectocervical lesions. However, cold-knife conization has a greater risk of bleeding compared with laser and LEEP conization. Moreover, cold-knife and laser conizations carry higher risks of cervical stenosis compared with LEEP conization (Baldauf, 1996; Houlard, 2002). Increasing patient age and depth of endocervical excision are significant cervical stenosis risks. Penna and co-workers (2005) noted a lower risk of stenosis in postmenopausal women using estrogen-replacement therapy compared with postmenopausal nonusers.

Conization of the cervix for the treatment of CIN has been associated with adverse outcomes in subsequent pregnancies, including preterm delivery, low-birth-weight infants, incompetent cervix, and cervical stenosis (Crane, 2003; Kristensen, 1993a, 1993b; Raio, 1997; Samson, 2005). Although there is no major difference in obstetric outcome among the three techniques, increased cone biopsy size has been shown to correlate positively with rates of preterm delivery and premature membrane rupture (Mathevet, 2003; Sadler, 2004). Cold-knife conization generally removes more cervical stroma than other excisional methods.

Cold-Knife Conization

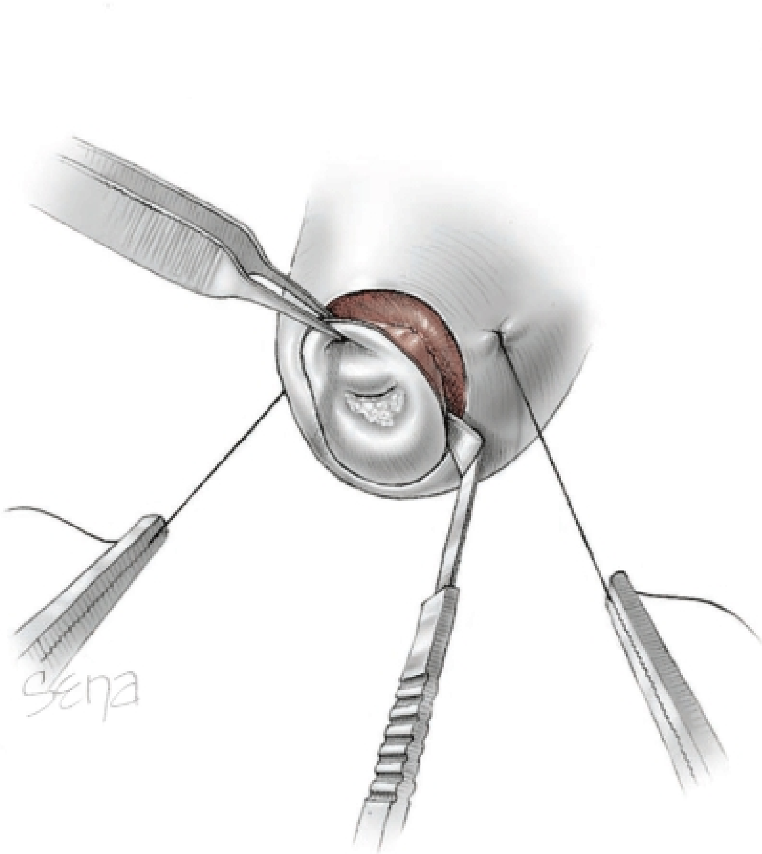
Surgical Steps

1. **Anesthesia and Patient Positioning.** For most women, cold-knife conization is a day-surgery procedure performed under general or regional anesthesia. Following administration of anesthesia, the patient is placed in the dorsal lithotomy position. The vagina is surgically prepared, the bladder is drained, and vaginal sidewalls are retracted to reveal the cervix. Areas of planned excision may be identified more easily following Lugol solution application (see Chap. 29, Lugol Solution).

2. **Injection of Vasoconstrictors.** Bleeding during cold-knife conization can be brisk and obscure the operating field. Accordingly, preventative steps can be taken both before and during surgery. First, vasoconstrictors as described for LEEP are injected circumferentially into the cervix. Additionally, descending cervical branches of the uterine arteries can be ligated with figure-of-eight sutures using a nonpermanent material placed along the lateral aspects of the cervix at 3 and 9 o'clock. After these knots are secured, the sutures are kept long and held by hemostats to manipulate the cervix.

3. **Conization.** A uterine sound or small-caliber uterine dilator is placed into the endocervical canal to orient the surgeon as to the depth and direction of the canal. Using a Beaver blade or a no. 11 blade, the surgeon initiates the incision on the lower lip of the cervix. This limits blood from obscuring the operative field. A Beaver blade is a triangular-shaped knife blade with a 45-degree bend and is useful for creating incisions at an angle. A circumscribing incision creates a 2- to 3-mm border around the entire lesion (Fig. 41-14.2). The 45-degree angle of the blade is directed centrally and cephalad to excise a conical specimen. Toothed forceps or tissue hooks may be used to retract the ectocervix during creation of the cone. Scalpel or Mayo scissors may be used to cut the tip of the cone and release the specimen. Following excision, an orienting suture is placed on the site of the specimen that corresponds to the 12 o'clock position in situ. This orientation is noted on a pathology requisition form.

FIGURE 41-14.2



Source: Schorge JO, Schaffer JI, Halvorson LM, Hoffman BL, Bradshaw KD, Cunningham FG: *Williams Gynecology*: http://www.accessmedicine.com

Conization incision.

4. **Endocervical Curettage.** Following removal of the cone specimen, endocervical curettage is performed to screen for residual disease distal to the excised cone apex (Husseinzadeh, 1989; Kobak, 1995).

5. **Hemostasis.** Following excision of the specimen, bleeding is common and can be controlled with individual suturing of isolated vessels, with electrosurgical coagulation, or with Sturmdorf sutures. In addition, a topical absorbable hemostat mesh (Surgicel Nu-knit, Johnson and Johnson, Piscataway, NJ) can be placed in the cone bed.

   Sturmdorf suturing is a running locked suture line that closes the cone bed by circumferentially folding the cut ectocervical edge inward toward the endocervix. This technique is less favored because of increased rates of postoperative dysmenorrhea, inadequate postoperative surveillance PAP smears, and concerns that the flap might conceal residual disease (Kristensen, 1990; Trimbos, 1983).

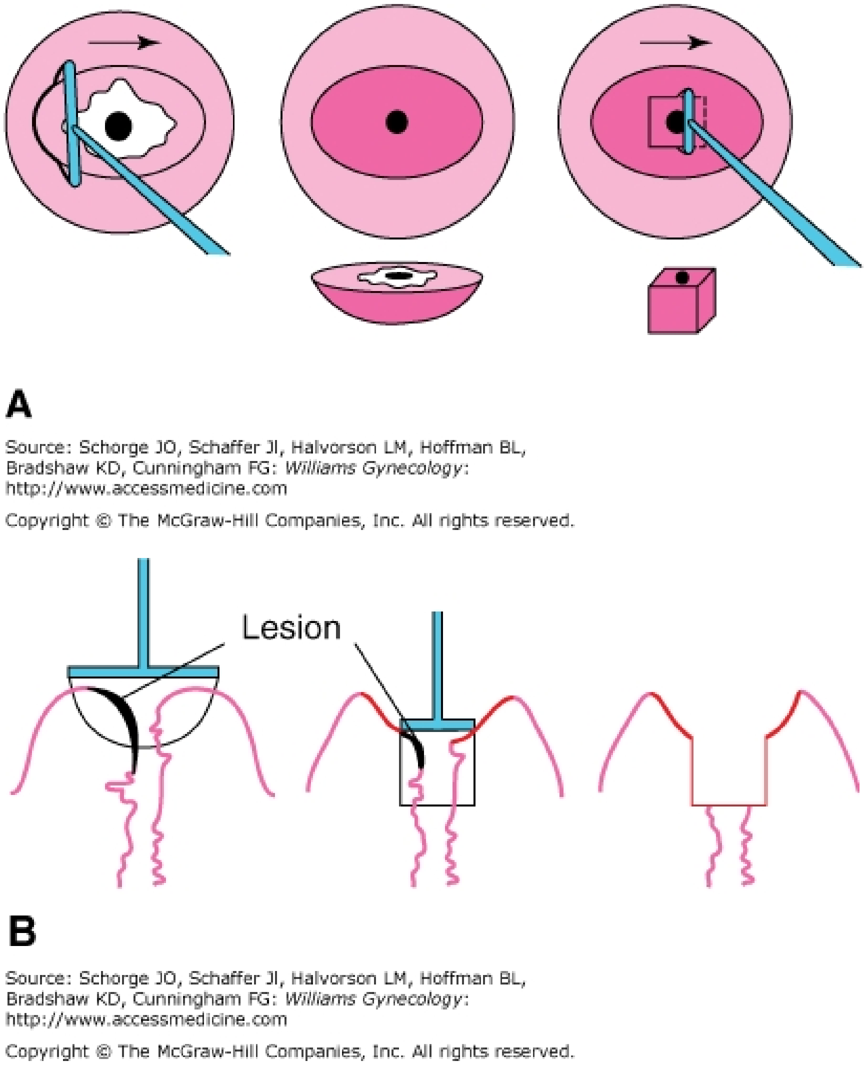
Loop Electrosurgical Excision Procedure Conization

Surgical Steps

The surgical steps for this more extensive LEEP mirror those used for excision of ectocervical lesions (Surgical Steps). However, to remove the endocervical canal, a deeper pass must be made through the cervical stroma. This may be accomplished with a single pass using a larger loop. Alternatively, in an effort to minimize the volume of tissue excised, a *tiered technique,* also known as *top-hat technique,* can be used. With this method, an initial pass is made to remove ectocervical lesions, as described previously (Fig. 41-13.5). To remove the endocervical canal, a second smaller loop is passed more deeply into the cervical stroma (Fig. 41-14.3).

As a result, the tissue is excised in two pieces and both are sent for evaluation.

FIGURE 41-14.3



Loop electrosurgical excision procedure (LEEP) "top hat" cervical conization procedure. **A.** View of procedure as seen through a speculum. Final specimen as two pieces. **B.** View is 90 degrees from that shown in A. The first pass is made with a round loop electrode. The deeper second pass is completed with a square loop electrode. Final shape of cervical conization bed.

Laser Conization

Excision of a laser cone-biopsy specimen uses similar techniques as those described for laser ablation (Surgical Steps). However, rather than ablating the involved tissue, laser energy is directed to cut and remove a cone-biopsy specimen. A higher wattage of 800 to 1200 W/cm^2 combined with a smaller laser spot size is used to create a cutting effect. A cone-shaped specimen then is excised. During excision of the cone specimen, nonreflective tissue hooks may be needed to retract the ectocervical edge away from the laser beam path and to create tissue tension along the plane of incision.

Postoperative

Recovery following all excisional methods is rapid and follows that for other surgeries of the cervix described previously (Postoperative). Patients require postoperative surveillance for identification of disease persistence or recurrence, and this is described in detail in Chapter 29, Further Cytologic and Colposcopic Surveillance.

41-15 WIDE LOCAL EXCISION OF VULVAR INTRAEPITHELIAL NEOPLASIA

With vulvar intraepithelial neoplasia (VIN), treatment goals include prevention of invasive vulvar cancer and, when possible, preservation of normal vulvar anatomy and function. Accordingly, although simple vulvectomy may be appropriate treatment in some cases, less extensive wide local excision of lesions and medical treatments described in Chapter 29, Management also have been evaluated as alternative options (Hillemanns, 2006).

Wide local excision of lesions is favored by many because it offers a tissue specimen for exclusion of invasive disease and confirmation of surgical margins and lowers patient morbidity. In patients in whom excision involves the clitoris, urethra, or anus, a combined surgical excision and laser ablation approach is sometimes helpful. This combined technique uses carbon dioxide (CO_2) laser therapy at sites where excision alone might lead to dysfunction or malformation (Cardosi, 2001).

Preoperative

PATIENT EVALUATION

Prior to excision, full evaluation of the lower reproductive tract for evidence of invasive disease should be completed as outlined in Chapter 29, Colposcopy.

CONSENT

Wide local excision of VIN successfully treats disease, and progression to invasive vulvar cancer is low (3 to 5 percent) (Jones, 2005; Rodolakis, 2003). However, VIN recurrence is common, and even in those with tissue margins negative for disease, recurrence ranges from 15 to 40 percent (Kuppers, 1997; Modesitt, 1998).

In the immunocompetent, surgical and postoperative risks are few and typically include wound infection or separation, chronic vulvodynia, dyspareunia, and scarring or altered vulvar appearance. Any vulvar operation requires thorough preoperative counseling regarding expectations for anatomic outcome and for sexual function.

Intraoperative

Surgical Steps

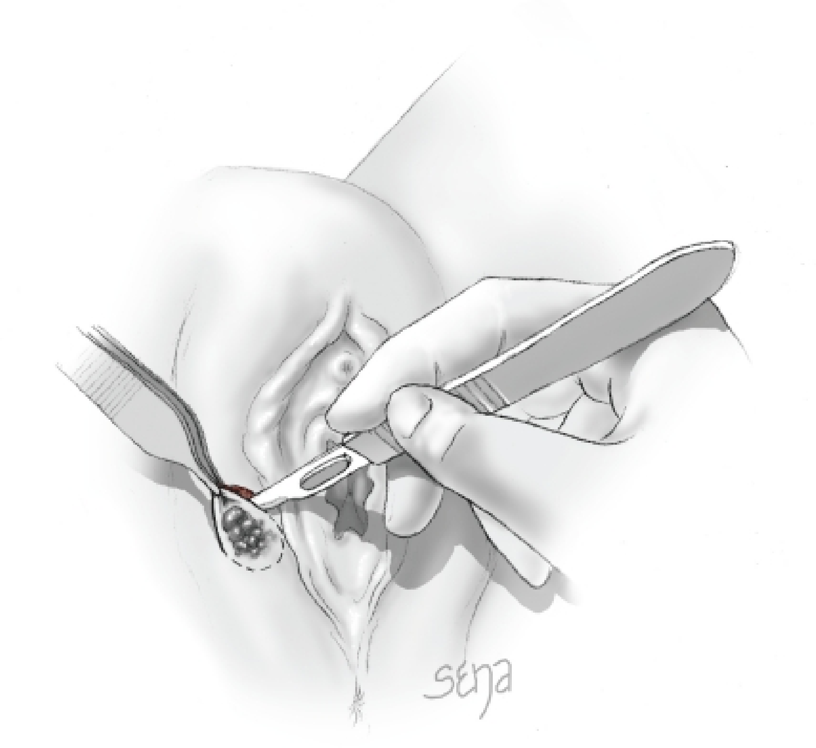
1. **Anesthesia and Patient Positioning.** The choice of anesthesia or analgesia will vary depending on the location and size of the lesion being treated. Whereas smaller and labial or perineal lesions may be excised easily using local analgesia in an office setting, larger lesions or those involving the urethra and clitoris may require general or regional anesthesia. The patient is placed in dorsal lithotomy position, and the vulva is surgically prepared.

2. **Lesion Identification.** Prior to incision, the area of excision should be well demarcated. Colposcopic examination following application of 3- to 5-percent acetic acid to the vulva will aid in identification of lesion margins. A 5-mm circumferential surgical margin surrounding the lesion is recommended by most (Joura, 2002). In the past, toluidine blue was used to stain nuclear chromatin and enhance vulvar lesions. However, normal tissue also can absorb the stain and distort true disease margins. Therefore, use of this stain is not recommended.

3. **Incision.** A scalpel in used to incise the lesion. Most VIN lesions fail to extend deeper than 2 mm on non-hair-bearing areas such as the labia minora. However, in hair-bearing areas of the vulva, VIN may extend to the deepest hair follicles (Fig. 41-15.1). This is generally deeper than 2 mm but not more than 4 mm. Thus, incision depth will vary depending on lesion location (Preti, 2005).

   Because disease recurrence is related to the presence or absence of disease-free surgical margins, frozen sections of the specimen margins can be evaluated intraoperatively (Friedrich, 1983).

FIGURE 41-15.1



Source: Schorge JO, Schaffer JI, Halvorson LM, Hoffman BL, Bradshaw KD, Cunningham FG: *Williams Gynecology*: http://www.accessmedicine.com

Vulvar incision.

4. **Margin Undermining.** To mobilize the wound edges for re-approximation, a surgeon undermines these edge margins sharply with fine scissors. Tissues should allow wound edge approximation without undue tension at the suture line.

5. **Wound Closure.** The edges of the skin then are reapproximated with interrupted stitches using 3-0 or 4-0 delayed-absorbable sutures.

Postoperative

Typically, without complication, recovery from wide local excision is rapid, and patients may resume normal activities as desired. Sitz baths and oral analgesics usually are recommended for the first week following surgery. Intercourse is delayed until wounds have fully healed, and this time will vary depending on wound site and size.

Because of the significant risk for VIN recurrence, postprocedural surveillance is essential, with colposcopic vulvar examination every 6 months for 2 years and then annually thereafter.

41-16 SHARP DILATATION AND CURETTAGE

Although used for diagnostic evaluation and treatment of abnormal uterine bleeding during the last 150 years, the indications for sharp dilatation and curettage (D&C) have decreased with the development of less invasive methods (see Chap. 8, Endometrial Biopsy). In the evaluation of abnormal uterine bleeding, sharp curettage may be used alone or more commonly in combination with

hysteroscopy for women with persistent bleeding despite normal findings with sonography and pipelle endometrial sampling. Moreover, when a stenotic cervical os prohibits in-office endometrial sampling, sharp D&C may be necessary to gain access to the uterine cavity. Additionally, in the treatment of severe acute menorrhagia, sharp D&C may be used to remove hypertrophic endometrium if bleeding is refractory to oral or intravenous estrogen administration. Although suction curettage is used more commonly for removal of products of first-trimester pregnancy, sharp D&C also may be an option. Finally, in case of suspected ectopic pregnancy, sharp D&C is sometimes used to document the absence of intrauterine trophoblastic tissue (see Chap. 7, Endometrial Sampling).

Preoperative

CONSENT

For most women, sharp D&C poses only a small risk of complication, and rates typically fall below 1 percent (Radman, 1963; Tabata, 2001). Among these, infection and uterine perforation are among the most common.

PATIENT PREPARATION

Because the indications for sharp D&C are diverse, diagnostic testing prior to evacuation will vary. Antibiotic administration prior to sharp D&C typically is not required. However, because pelvic infection may follow this procedure, antibiotics usually are prescribed postoperatively. Doxycycline 100 mg orally twice daily for 10 days is given commonly. The risk of bowel injury with this procedure is slight, and thus preoperative enemas are not mandatory.

Intraoperative

Surgical Steps

1. **Anesthesia and Patient Positioning.** Sharp D&C typically is performed as an outpatient procedure under general or regional anesthesia or with local nerve blockade combined with intravenous sedation. The patient is placed in the dorsal lithotomy position, the vagina is surgically prepared, and the bladder is drained.

   A bimanual examination to determine uterine size and inclination is performed prior to introduction of vaginal instruments. This step allows instruments to be inserted along the long axis of the uterus to avoid perforation.

2. **Uterine Sounding.** Suitable vaginal exposure can be achieved with either a Graves speculum or individual vaginal retractors. The anterior lip of the cervix is grasped with a single-tooth tenaculum to stabilize the uterus during sharp D&C (Fig. 40-21). A Simpson uterine sound then is held as a pencil with the thumb and first two fingers (Fig. 41-16.1). The sound is guided slowly through the cervical os, into the uterine cavity, and up to the fundus. Importantly, instruments should not be forced because this increases the risk of perforation.

   Once gentle resistance is met at the fundus, the distance from the fundus to the external os is measured by score marks along the length of the sound. Knowledge of the depth to which dilators and curettes can be inserted safely decreases the risk of uterine perforation.

   At times, cervical stenosis may preclude easy access to the endocervical canal. In these cases, smaller-caliber tools, such as a lacrimal duct probe, may be guided into the external cervical os to define the canal path. Sonography may be helpful when done simultaneously with sharp D&C in these situations. Visualization of instruments by sonography as they are being passed may help to ensure proper placement. In addition, for stenosis, pretreatment with the prostaglandin E1 analog misoprostol (Cytotec, Pharmacia, Morpeth, UK), 100 mg orally the night before and morning of biopsy may allow adequate cervical softening for instrument passage.

FIGURE 41-16.1

Source: Schorge JO, Schaffer JI, Halvorson LM, Hoffman BL, Bradshaw KD, Cunningham FG: *Williams Gynecology*: http://www.accessmedicine.com

Sims uterine sound.

3. **Uterine Dilatation.** Following sounding, dilators of sequentially increasing caliber are inserted to open the endocervical canal and internal cervical os. A Hegar, Hank, or Pratt dilator (see Fig. 41-17.4) is held by the thumb and first two fingers while the fourth and fifth fingers and heel of the hand rest on the perineum and buttock (Fig. 41-17.5). Each dilator is advanced gently and gradually through the internal cervical os. Serial dilatation continues until the cervix will admit the selected curette (Fig. 41-16.2).

   During sounding or dilatation, uterine perforation may occur and is suspected when the instrument travels deeper than previously measured. Because of the blunt, narrow shape of these tools, risk of significant uterine or abdominal organ injury is low. In such cases, if significant bleeding is absent, re-assessment of uterine inclination and completion of the sharp D&C are reasonable. Alternatively, surgery may be terminated and repeated at a later date, thus allowing myometrial healing.

FIGURE 41-16.2

Source: Schorge JO, Schaffer JI, Halvorson LM, Hoffman BL, Bradshaw KD, Cunningham FG: *Williams Gynecology*: http://www.accessmedicine.com

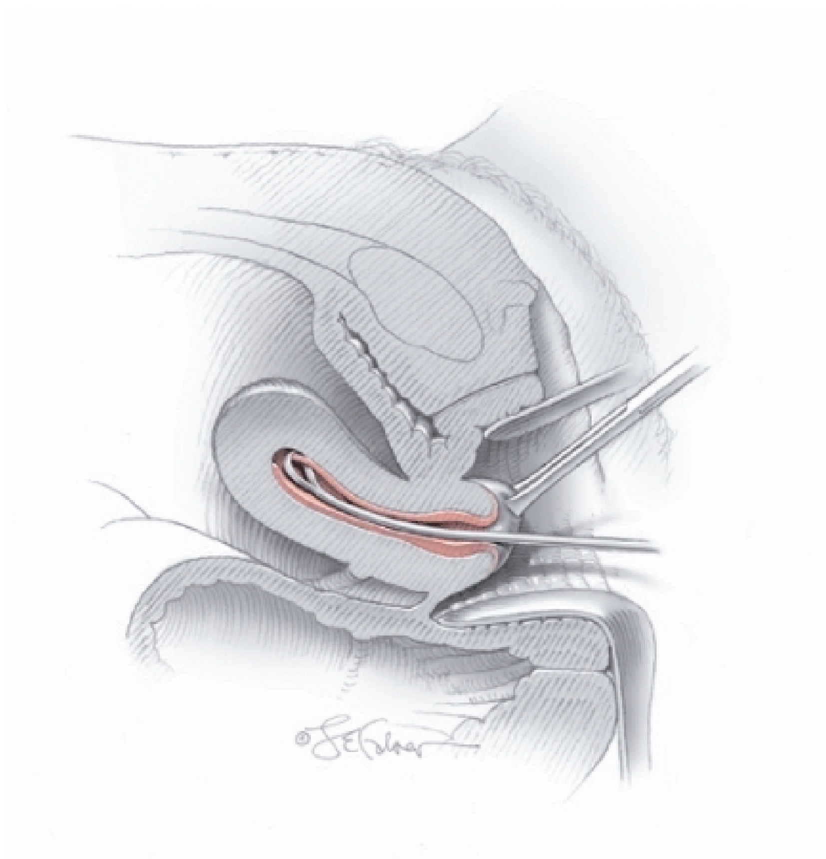
Uterine curette.

4. **Uterine Curettage.** Prior to curettage, a sheet of nonadherent wound dressing material (Telfa, The Kendall Company, Mansfield, MA) is spread out in the vagina beneath the cervix. The uterine curette then is inserted and advanced to the fundus, following the long axis of the corpus. On reaching the fundus, the sharp surface of the curette is positioned to contact the adjacent endometrium (Fig. 41-16.3). Pressure is exerted against the endometrium as the curette is pulled toward the internal cervical os.

   After reaching the os, the curette is redirected to the fundus and positioned immediately adjacent to the path of the first curettage pass. In this manner, the surgeon attempts to sample the entire uterine surface. After several serial passes, tissues collected in the isthmus region are scraped out onto the Telfa pad.

   As with dilatation, the uterus may be perforated during curettage. However, the sharp curette has the potential to lacerate bowel, vessels, and other abdominal organs. Accordingly, diagnostic laparoscopy is suggested to evaluate for such injuries.

FIGURE 41-16.3



Source: Schorge JO, Schaffer JI, Halvorson LM, Hoffman BL, Bradshaw KD, Cunningham FG: *Williams Gynecology*: http://www.accessmedicine.com

Uterine curettage.

5. **Uterine Exploration.** Because uterine polyps, both large and small, may be missed with sharp curettage, uterine exploration with Randall kidney stone forceps is warranted in women undergoing evaluation of abnormal bleeding. Closed forceps are inserted into the endometrial cavity. On reaching the fundus, the forceps are opened against the uterine walls, closed, and then pulled away from the endometrium. In this fashion, anterior, posterior, proximal, and distal cavity surfaces are explored. With capture of a polyp within the jaws, a tug against the closed forceps is felt as they are pulled away from the uterine wall. Firm traction typically frees the polyp.

   Alternatively, hysteroscopy may be used adjunctively with curettage to diagnose and remove focal lesions such as polyps.

Postoperative

Recovery from sharp D&C is typically fast and without complication. Light bleeding or spotting is expected, and patients may resume normal activities at their individual paces.

41-17 SUCTION DILATATION AND CURETTAGE

Suction dilatation and curettage (D&C) is the most common method used to remove first-trimester products of conception (see Chap. 6, Surgical Abortion). Vacuum aspiration, the most common form of suction curettage, requires a rigid cannula attached to an electric-powered vacuum source. Alternatively, manual vacuum aspiration uses a similar cannula that attaches to a hand-held

syringe for its vacuum source (MacIsaac, 2000; Masch, 2005).

Preoperative

PATIENT EVALUATION

For most women, suction D&C is preceded by transvaginal sonography. As discussed in Chapter 6, Threatened Abortion, this imaging modality aids in documenting pregnancy viability, location, and size. In addition to sonographic evaluation, blood typing is performed to assess Rh status. Administration of 50 or 300 µg (1,500 IU) Rho [D] immune globulin intramuscularly within 72 hours of pregnancy termination in Rh-negative women can lower the risk of isoimmunization in future pregnancies dramatically.

CONSENT

Suction D&C is a safe and effective method of uterine evacuation (Forna, 2001). Short-term complication rates are low and have been cited at 1 to 5 percent (Hakin-Elahi, 1990; Zhou, 2002). Complications include uterine perforation, retained products, infection, and hemorrhage, and rates increase after the first trimester. Accordingly, sharp or suction D&C ideally should be performed before 14 to 15 weeks' gestation.

The incidence of uterine perforation associated with elective abortion varies. Two important determinants are the skill of the physician and position of the uterus. Rates of perforation increase with a retroverted uterus and a less experienced surgeon. Much greater likelihood of perforation if the uterus is retroverted. Accidental uterine perforation usually is recognized when the instrument passes without resistance deep into the pelvis. Observation may be sufficient if the uterine perforation is small, such as when produced by a uterine sound or narrow dilator. Considerable intra-abdominal damage, however, can be caused by instrumentsâ€”especially suction and sharp curettesâ€”passed through a uterine defect into the peritoneal cavity (Keegan, 1982). Because unrecognized bowel injury can cause severe peritonitis and sepsis, laparoscopy or laparotomy to examine the abdominal contents is often the safest course of action in these cases (Kambiss, 2000).

Rarely, women may develop cervical incompetence or intrauterine adhesions following D&C. Those contemplating abortion should understand the potential for these rare but serious complications.

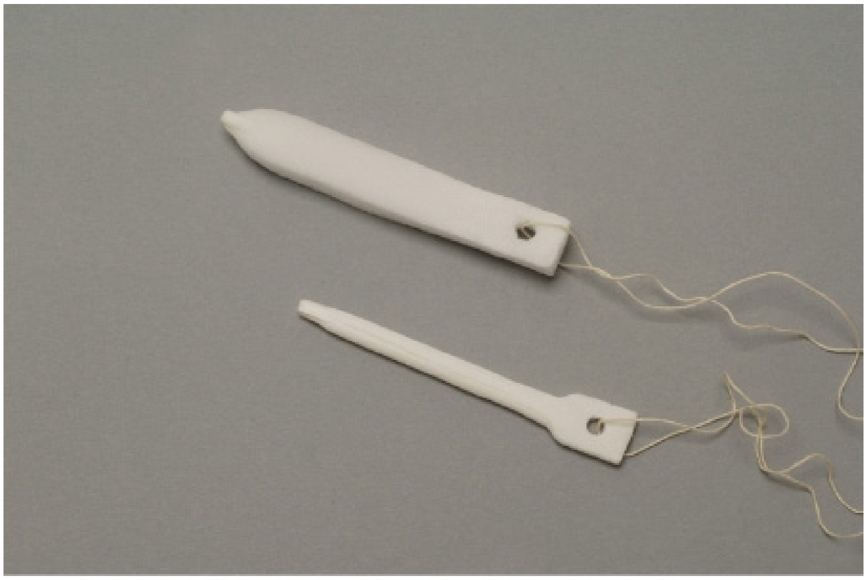
PATIENT PREPARATION

Suction D&C may be performed for cases of incomplete or inevitable abortion and require no cervical dilatation for procedure completion. However, other settings require manual dilatation of the cervical os with metal dilators, a procedural step closely associated with uterine perforation and patient discomfort. Therefore, to obviate this need, hygroscopic dilators may be placed in the endocervical canal to the level of the internal os to accomplish cervical dilatation.

Hygroscopic dilators draw water from cervical tissues and expand, which gradually dilates the cervix. One type of hygroscopic dilator originates from the stems of *Laminaria digitata* or *Laminaria japonica,* a brown seaweed. The stems are cut, peeled, shaped, dried, sterilized, and packaged according to their hydrated sizeâ€”small, 3 to 5 mm diameter; medium, 6 to 8 mm; and large, 8 to 10 mm. The strongly hygroscopic laminaria presumably act by drawing water from cervical proteoglycan complexes. The complexes dissociate and thereby allow the cervix to soften and dilate.

Another device available is the synthetic hygroscopic dilator, Lamicel, which is a similarly shaped polyvinyl alcohol polymer sponge impregnated with anhydrous magnesium sulfate (Fig. 41-17.1).

FIGURE 41-17.1



Source: Schorge JO, Schaffer JI, Halvorson LM, Hoffman BL, Bradshaw KD, Cunningham FG: *Williams Gynecology*: http://www.accessmedicine.com

Expanded laminaria (above) and dry laminaria (below).

For placement of the dilators, the cervix is cleansed with povidone-iodine solution and is grasped anteriorly with a tenaculum. A laminaria of appropriate size then is inserted using a uterine packing forceps so that the tip rests at the level of the internal os (Fig. 41-17.2). After 4 to 6 hours, the laminaria will have swollen to dilate the cervix sufficiently and allow easier mechanical D&C. Cramping frequently accompanies expansion of the laminaria.

In addition to hygroscopic dilators, various prostaglandin preparations have been investigated to soften the cervix for subsequent dilation. Misoprostol has been used effectively to induce uterine evacuation in properly selected patients. Studies investigating its use preoperatively to ease or obviate cervical dilatation, however, have not found it consistently effective in this clinical setting (Bunnasathiansri, 2004; Sharma, 2005).

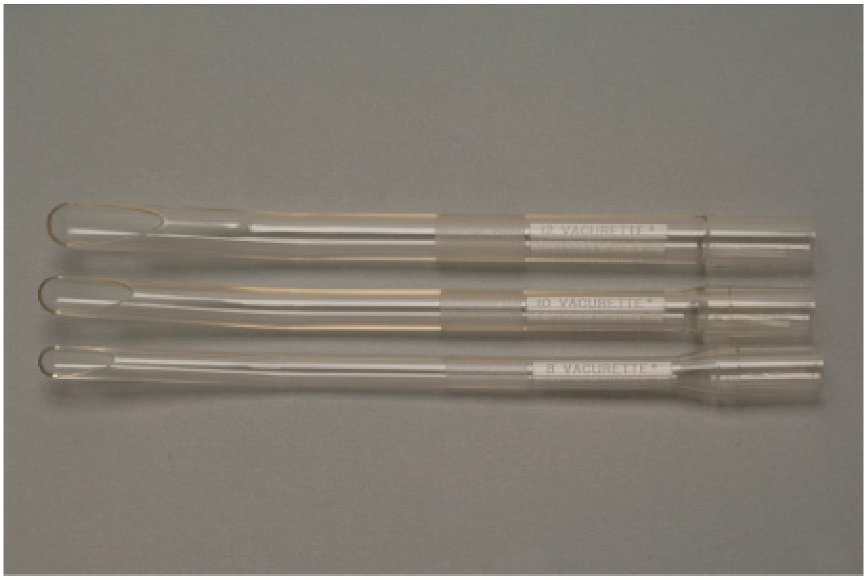
Antibiotic prophylaxis should be provided at the time of transcervical surgical abortion. Based on their review of 11 randomized trials, Sawaya and associates (1996) concluded that perioperative antibiotics decreased the risk of infection by 40 percent. Although no regimen appears superior to others, a convenient, inexpensive, and effective one is doxycycline 100 mg orally twice daily for 10 days.

Intraoperative

INSTRUMENTS

Suction D&C requires an electric suction unit; stiff, translucent, large-bore sterile suction tubing; and sterile Karman suction cannulas (Fig. 41-17.3). Plastic suction cannulas are available in varying diameters. Choosing the most appropriately sized cannula balances competing factors. Small cannulas risk retained intrauterine tissue postoperatively, whereas large cannulas risk cervical injury and more discomfort. For most first-trimester evacuations, a no. 8 to 12 Karman cannula is sufficient.

FIGURE 41-17.3



Source: Schorge JO, Schaffer JI, Halvorson LM, Hoffman BL, Bradshaw KD, Cunningham FG: *Williams Gynecology*: http://www.accessmedicine.com

Karmen cannulas (sizes 4 to 12 mm).

Surgical Steps

1. **Anesthesia and Patient Positioning.** In the absence of maternal systemic disease, abortion procedures do not require hospitalization. When abortion is performed outside a hospital setting, capabilities for cardiopulmonary resuscitation and for immediate transfer to a hospital must be available. Anesthesia or analgesia used may vary and includes general anesthesia, paracervical block plus intravenous sedation, or intravenous sedation alone. After delivery of anesthesia or analgesia, the patient is placed in dorsal lithotomy position, the bladder is drained, and the vulva and vagina are surgically prepped.

2. **Uterine Sounding.** A Simpson uterine sound is placed through the os and into the uterine cavity to measure the depth and inclination of the uterine cavity prior to dilatation (Fig. 41-16.1).

3. **Cervical Dilatation.** A Graves speculum is placed in the vagina to allow access to the cervix. In cases of incomplete or inevitable abortion, the cervical os already will be dilated. Alternatively, metal Pratt, Hegar, or Hank dilators (Fig. 41-17.4) of sequentially increasing diameter are placed through the external and internal os to gently dilate the cervix. The uterus is especially vulnerable to perforation during this step. For this reason, the metal dilator should be grasped as one would a pencil. The heel of the hand and fourth and fifth fingers rest on the perineum and buttock. Gentle pressure from only the thumb and first two fingers is used to push the dilator through the cervical os (Fig. 41-17.5).

FIGURE 41-17.4

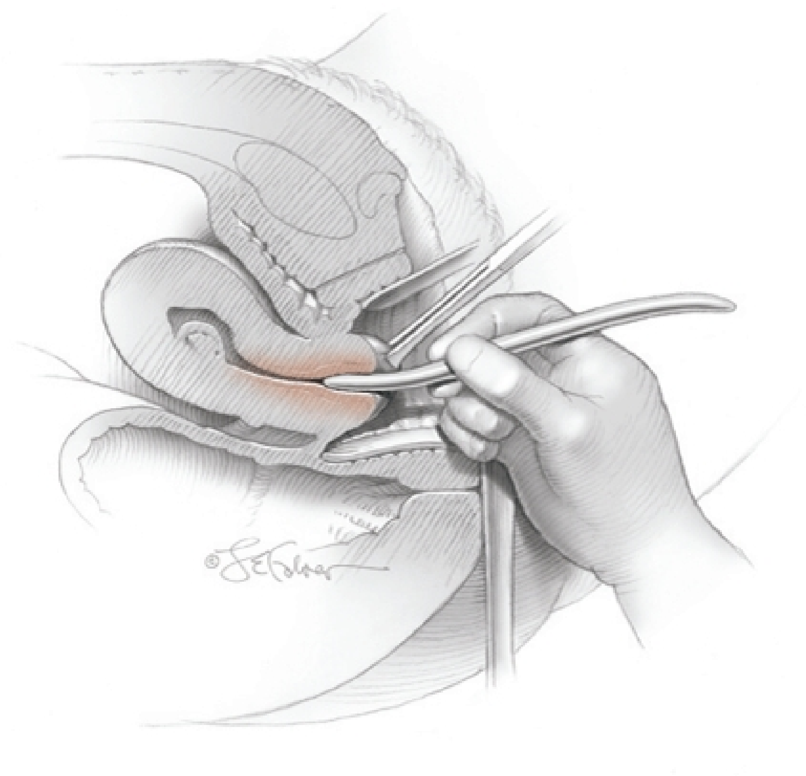
Pratt dilators of serially increasing diameter.

FIGURE 41-17.5



Source: Schorge JO, Schaffer JI, Halvorson LM, Hoffman BL, Bradshaw KD, Cunningham FG: *Williams Gynecology*: http://www.accessmedicine.com

Uterine dilatation.

4. **Uterine Evacuation.** The cannula is inserted through the open cervix and into the endometrial cavity. The suction unit is turned on, and uterine contents are removed. The suction cannula is moved toward the fundus and then back toward the os and is turned circumferentially to cover the entire surface of the uterine cavity.

   Tissue is collected in a container at the distal end of the tubing and is sent for pathologic evaluation to exclude hydatidiform mole. Occasionally, the Karman cannula may become obstructed with excess tissue. The suction unit is turned off prior to cannula removal. Once the cannula opening is cleared of obstructing tissue, it may be reinserted, and curettage completed.

5. **Sharp Curettage.** Although no more tissue is aspirated, a gentle sharp curettage should follow to remove any remaining placental or fetal fragments (see Section 41-6, Bartholin Gland Duct Incision and Drainage).

Postoperative

Recovery from suction D&C is typically fast and without complication. Patients may resume normal activities as they desire, but abstinence from intercourse usually is encouraged during the first week following surgery.

Ovulation may resume as early as 2 weeks after an early pregnancy ends. Therefore, if contraception is desired, methods should be initiated soon after abortion.

41-18 MYOMECTOMY

Myomectomy involves surgical removal of leiomyomas from their surrounding myometrium in an attempt to resolve abnormal

uterine bleeding, pelvic pain, and infertility. For these problems, approximately 500,000 myomectomies were performed in the United States from 1979 to 2001. Although surgeons performed hysterectomies at nearly 12 times this frequency within the same time period, myomectomy rates still nearly doubled (Burrows, 2005). Suggested causes for this increased rate of organ preservation include a delay in childbearing and concern about sexual dysfunction following hysterectomy (see Section 41-19, Hysterectomy).

Myomectomy typically requires laparotomy. However, laparoscopic excision may be performed by those with skills in laparoscopic suturing and suture ligation.

Preoperative

PATIENT EVALUATION

Because of their impact on preoperative and intraoperative planning, leiomyoma size, number, and location should be evaluated prior to surgery. Sonography, magnetic resonance (MR) imaging, or hysteroscopy may be used, as described in Chapter 9, Imaging. For example, submucous tumors are removed more easily hysteroscopically (see Section 41-37, Hysteroscopic Myomectomy), whereas intramural and serosal types typically require laparotomy. Leiomyomas may be small and buried within the myometrium. Therefore, accurate information as to leiomyoma number and location ensures complete excision. Lastly, multiple large tumors or those that are located in the broad ligament, near the cornua, or involving the cervix may increase the risk of conversion to hysterectomy, and patients should be so counseled.

CONSENT

Myomectomy has several risks, including significant bleeding and transfusion. Moreover, uncontrolled hemorrhage or extensive myometrial injury during tumor removal may force hysterectomy. Fortunately, rates of conversion to hysterectomy during myomectomy are low and range from 0 to 2 percent (Iverson, 1996; LaMorte, 1993; Sawin, 2000). Postoperatively, the risk of adhesion formation is significant, and leiomyomas can recur.

PATIENT PREPARATION

Hematologic Status

Menorrhagia is a common indication for myomectomy. As a result, many women who elect to undergo this surgery are anemic. In addition, significant intraoperative blood loss during myomectomy is possible (Iverson, 1996, LaMorte, 1993; Sawin, 2000).

For these reasons, attempts to resolve anemia and bleeding prior to surgery should be pursued. Toward this goal, oral iron therapy and gonadotropin-releasing hormone (GnRH) agonists may have benefits (see Chap. 9, GnRH Agonists). Benagiano and associates (1996) administered oral iron therapy alone or in combination with GnRH agonists and found the combination of the two to be significantly more effective in correcting preoperative anemia than either agonist use or iron therapy alone.

GnRH Agonists

In addition to control of preoperative menorrhagia, these agents have been shown to decrease uterine volume significantly after several months use (Benagiano, 1996; Friedman, 1991). As a result, decreased uterine size following treatment may allow a less invasive surgical procedure. For example, myomectomy may be completed through a smaller laparotomy incision or by laparoscopy or hysteroscopy (Crosignani, 1996; Lethaby, 2005; Mencaglia, 1993; Stovall, 1994). These agents also have been found to diminish leiomyoma vascularity and uterine blood flow (Matta, 1988; Reinsch, 1994). A final benefit may be adhesion prevention. Imai and associates (2003) noted lower rates of adhesion formation at second-look laparoscopy in women undergoing myomectomy who had received preoperative GnRH agonist therapy.

The use of preoperative GnRH agonists, however, also may have disadvantages. Within leiomyomas, GnRH agonists can incite hyaline or hydropic degeneration, which may obliterate the pseudocapsule connective tissue interface between the tumor and the myometrium. Such obliterated cleavage planes may lead to tedious and lengthy enucleation (Deligdish, 1997). Moreover, studies have shown higher rates of leiomyoma recurrence in women treated with GnRH agonists prior to myomectomy (Fedele, 1990; Vercellini, 2003). Leiomyomas treated with these agents may shrink in volume and be missed during surgical removal.

For these reasons, GnRH agonists should not be used routinely in all patients undergoing myomectomy. These can be

recommended for preoperative use in women with greatly enlarged uteri or preoperative anemia or in cases in which a decrease in uterine volume would allow a less invasive approach to leiomyoma removal (Broekmans, 1996; Lethaby, 2002).

Autologous Blood Donation

The risk of blood transfusion varies among studies and ranges from less than 5 percent to nearly 40 percent (Darwish, 2005; LaMorte, 1993; Sawin, 2000; Smith, 1990). For this reason, in cases involving large uteri, especially those with multiple leiomyomas, autologous blood donation may be considered. Similarly, "cell saver" blood scavenger and reuse techniques have been advocated (Yamada, 1997). Indication, benefits, and limitations to these forms of transfusion are discussed more fully in Chapter 40, Fluid Resuscitation and Blood Transfusion.

Preoperative Uterine Artery Embolization (UAE)

This is an angiographic interventional procedure that delivers obstructing particles via catheter into both uterine arteries (see Fig. 9-8). Vessels serving leiomyomas have a larger caliber and particles are preferentially directed to the tumors, sparing the surrounding myometrium. For this reason, UAE can be performed preoperatively to lower intraoperative blood losses during myomectomy.

Several disadvantages have been noted with UAE, including collateral infarction of adjacent tissue and complications in subsequent pregnancies (see Chap. 9, Uterine Artery Embolization). For these reasons, preoperative UAE may best be limited to women with large uteri in whom excess blood loss is expected and in those not seeking future pregnancy.

Antibiotic Prophylaxis

There are few studies addressing the benefits of preoperative antibiotic use prior to myomectomy. Iverson and co-workers (1996), in their analysis of 101 myomectomy patients, found that although 54 percent of patients received prophylaxis, infectious morbidity was not lower in these women than in those in whom antibiotics were not used.

In myomectomy performed for infertility, because of the potential for tubal adhesions associated with pelvic infection, antibiotic prophylaxis has been advocated (Chelmow, 2005). For patients in whom prophylaxis is planned, 1 g of a first- or second-generation cephalosporin is appropriate (Iverson, 1996, Periti, 1988, Sawin, 2000).

Bowel Preparation

Because of the low risk of bowel injury with this procedure, bowel preparation typically is not required unless extensive adhesions are anticipated. In contrast, because the risk of conversion to hysterectomy is present, vaginal preparation immediately prior to surgical draping is warranted.

Intraoperative

Surgical Steps

1. **Anesthesia and Patient Positioning.** Myomectomy performed through a laparotomy incision is typically an inpatient procedure performed under general or regional anesthesia. The patient is placed supine, the vagina and abdomen are surgically prepped, and a Foley catheter is placed.

2. **Abdominal Entry.** A Pfannenstiel incision typically is appropriate for uteri 14 weeks in size or smaller (see Section 41-2, Pfannenstiel Incision). Larger uteri usually require a vertical midline abdominal incision.

3. **Leiomyoma Identification.** Following abdominal entry, the surgeon should inspect the serosal surface to identify leiomyomas to be removed. Additionally, firm palpation of the myometrium before and during the surgery will help to identify intramural or submucous leiomyomas.

4. **Use of Uterine Tourniquet.** Tourniquets have been used for years to temporarily occlude blood flow through the uterine arteries. Because the uterus receives collateral flow through the ovarian arteries, some tourniquet techniques include occlusion of both uterine and ovarian vessels. To compress the uterine arteries, bilateral windows are created in the leaves of the broad ligament at the level of the internal cervical os. A Penrose drain or Foley catheter is threaded through the opening

to encircle the uterine isthmus. Once in place, the Penrose drain is tied or the ends of the Foley catheter are clamped to compress the uterine vessels. In combination with this, occlusion of the utero-ovarian ligaments or infundibulopelvic ligaments has been described (Delancey, 1992; Sapmaz, 2003; Taylor, 2005). Large, bulky uteri or those with leiomyomas in the broad ligament, however, may limit the use of tourniquets in some patients. In addition to temporary occlusion of the uterine arteries, permanent ligation of the uterine arteries has been described and shown to lower blood loss during myomectomy (Liu, 2004; Taylor, 2005).

5. **Use of Vasopressin.** 8-Arginine vasopressin (Pitressin, Parke Davis Co., Morris Plains, NJ) is a sterile aqueous solution of synthetic vasopressin. It is effective in limiting uterine blood loss during myomectomy because of its ability to cause vascular spasm and uterine muscle contraction. Compared with placebo, 8-arginine vasopressin injection has been shown to decrease blood loss significantly during myomectomy (Frederick, 1994). Compared with tourniquet techniques, 8-arginine vasopressin injection also has been associated with either comparable or less intraoperative blood loss and with equally low patient morbidity (Fletcher, 1996; Ginsburg, 1993). Moreover, Darwish and colleagues (2005) found lower rates of myometrial hematoma formation in those using 8-arginine vasopressin compared with those using tourniquet techniques.

   Each vial of 8-arginine vasopressin is standardized to contain 20 pressor units/mL, and doses used for myomectomy range from 20 units diluted in 20 to 50 mL of saline (Bieber, 1998; Fletcher, 1996; Iverson, 1996). 8-Arginine vasopressin typically is injected along the planned serosal incision(s). The plasma half-life of this agent is 10 to 20 minutes. For this reason, injection of vasopressin should be discontinued 20 minutes prior to uterine repair to allow evaluation of bleeding from myometrial incisions (Hutchins, 1996).

   The main risks associated with local vasopressin injection result from inadvertent intravascular infiltration and include transient increases in blood pressure, bradycardia, atrioventricular block, and pulmonary edema (Deschamps, 2005; Tulandi, 1996). For these reasons, patients with a medical history of angina, myocardial infarction, cardiomyopathy, congestive heart failure, uncontrolled hypertension, migraine, asthma, and severe chronic obstructive pulmonary disease may not be candidates for 8-arginine vasopressin use.

6. **Serosal Incision.** Because of postoperative adhesion formation risks, surgeons should minimize the number of serosal incisions and attempt to place incisions on the anterior uterine wall. Tulandi and colleagues (1993) found that posterior wall incisions result in a 94-percent adhesion formation rate compared with a 55-percent rate for anterior incisions.

   For most patients, a midline vertical uterine incision allows removal of the greatest number of leiomyomas through the fewest incisions. The length should accommodate the approximate diameter of the largest tumor. The incision depth should afford access to all leiomyomas (Fig. 41-18.1). To reach lateral tumors, a surgeon may create lateral myometrial incisions within the initial central incision (see Fig. 41-18.4). However at times, separate incision may be required to excise tumors from these locations.

FIGURE 41-18.1

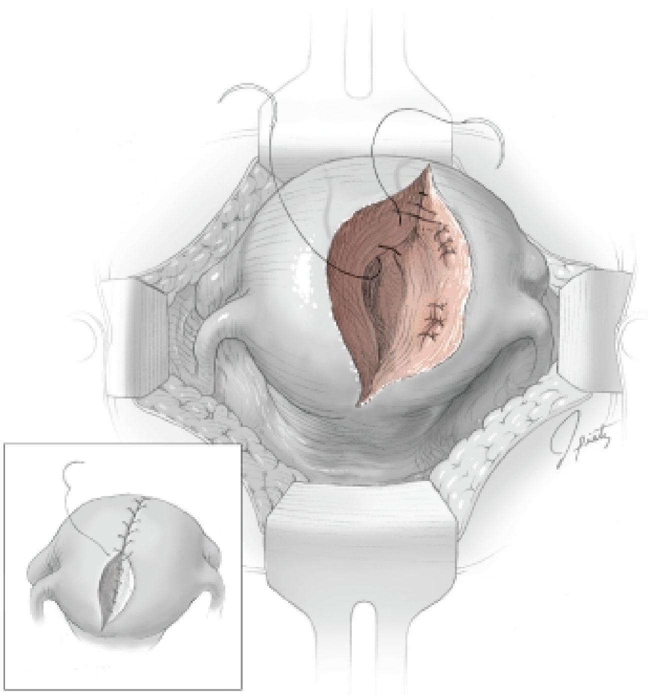
Uterine incision.

FIGURE 41-18.4

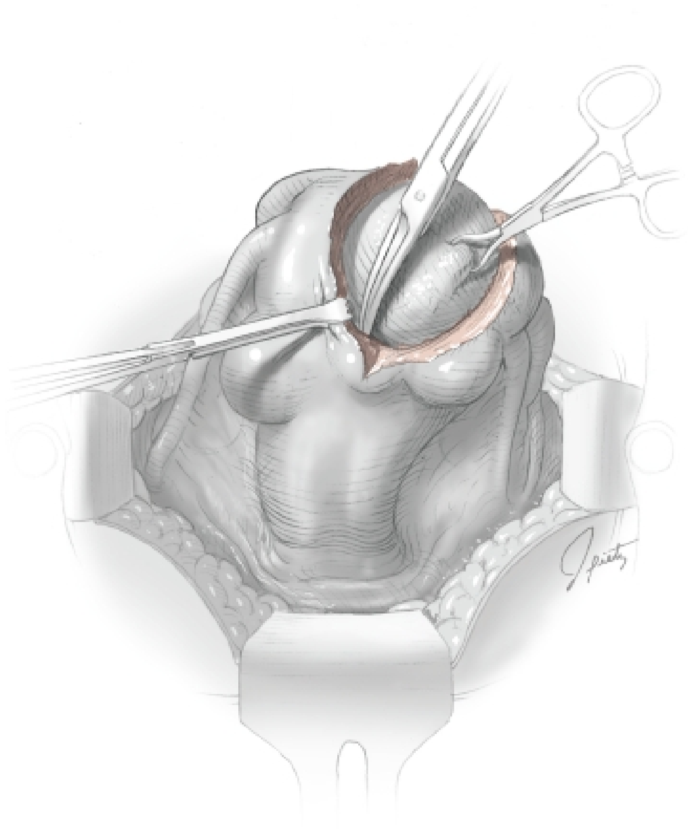


Source: Schorge JO, Schaffer JI, Halvorson LM, Hoffman BL, Bradshaw KD, Cunningham FG: *Williams Gynecology*: http://www.accessmedicine.com

Uterine incision closure.

7. **Tumor Enucleation.** The first leiomyoma is grasped with a Lahey or single-toothed tenaculum (Fig. 41-18.2). Alternatively, a leiomyoma screw also can be use to achieve tissue traction and create tissue tension between the myometrium and leiomyoma. Sharp and blunt dissection of the pseudocapsule surrounding the leiomyoma frees the tumor from the adjacent myometrium.

FIGURE 41-18.2

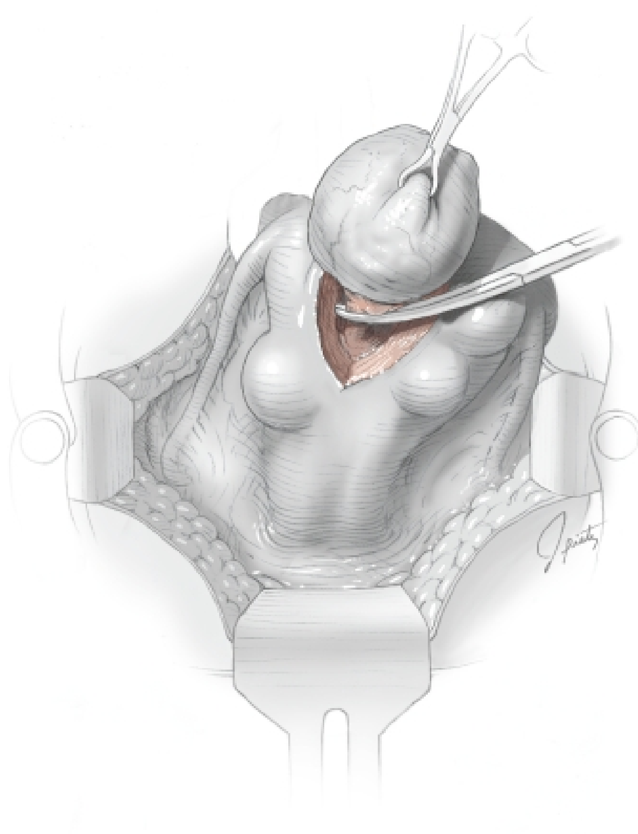


Source: Schorge JO, Schaffer JI, Halvorson LM, Hoffman BL, Bradshaw KD, Cunningham FG: *Williams Gynecology*: http://www.accessmedicine.com

Tumor enucleation.

8. **Bleeding.** Hemorrhage during myomectomy develops primarily during tumor enucleation and is correlated positively with preoperative uterine size, total weight of leiomyomas removed, and operating time (Ginsburg, 1993). Approximately two to four main arteries feed each leiomyoma and enter the tumor at unpredictable sites (see Fig. 9-2). For this reason, surgeons must watch for these vessels, ligate them prior to transection when possible, and be ready to grasp them immediately with hemostats for ligation or fulgaration if they are lacerated during tumor excision (Fig. 41-18.3).

FIGURE 41-18.3



Source: Schorge JO, Schaffer JI, Halvorson LM, Hoffman BL, Bradshaw KD, Cunningham FG: *Williams Gynecology*: http://www.accessmedicine.com

Vessel ligation.

9. **Myometrial Incision.** Smaller internal incisions into the myometrium may be required to excise all leiomyomas. If the endometrial cavity is entered, it should be closed with a running suture of 4-0 or 5-0 delayed-absorbable suture.

10. **Myometrial Closure.** Following removal of all tumors, redundant serosa may be excised. Smaller internal myometrial incisions are closed first with delayed-absorbable suture (Fig. 41-18.4). The myometrium then is closed in layers to improve hemostasis and prevent hematoma formation. A gauge of sufficient strength to prevent breakage during muscle approximation is selected, typically 0 to 2-0.

11. **Serosal Closure.** Closure of the serosal incision using a running baseball suture with 4-0 or 5-0 monofilament delayed-absorbable suture may help to limit adhesion formation (Fig. 41-18.4, inset). In addition, absorbable adhesion barriers such as Interceed (Ethicon, Piscataway, NJ) have been shown to reduce the incidence of adhesion formation following myomectomy (Farquhar, 2000). Mettler and co-workers (2004) in a German trial showed a 65-percent reduction in adhesions following myomectomy using SprayGel (Confluent Surgical, Waltham, MA), an adhesion barrier.

Postoperative

Following abdominal myomectomy, postoperative care follows that for any major abdominal surgery. Hospitalization typically varies from 1 to 4 days, and return of normal bowel function and febrile morbidity usually dictate this course. Postoperative activity in

general can be individualized, although vigorous exercise usually is delayed until 4 to 6 weeks after surgery.

FEVER

Febrile morbidity of greater than 38.0Â°C is a common event following myomectomy (Darwish, 2005; Iverson, 1996; LaMorte, 1993). Purported causes include atelectasis, myometrial incisional hematomas, and factors released with myometrial destruction. Although fever is common following myomectomy, pelvic infection is not. For example, LaMorte and colleagues (1993) noted only a 2-percent rate of pelvic infection in their analysis of 128 myomectomy patients.

SUBSEQUENT PREGNANCY

There are no clear guidelines as to the timing of pregnancy attempts following myomectomy. Darwish and colleagues (2005) performed sonographic examinations on 169 patients following myomectomy. Following myometrial indicators, they concluded that wound healing usually is completed within 3 months.

41-19 HYSTERECTOMY

Hysterectomy is one of the most frequently performed gynecologic procedures, with approximately 600,000 women undergoing this procedure annually in the United States (Farquhar, 2002; Kozak, 2002). The reasons for hysterectomy are varied and include both benign and malignant etiologies. Of benign indications, symptomatic leiomyomas and pelvic organ prolapse are the most frequent, although abnormal bleeding, endometriosis, chronic pain, and premalignant neoplasia are also relatively common.

Preoperative

PATIENT EVALUATION

A spectrum of tests may be required to reach the preoperative diagnosis. These tests vary depending on the clinical setting and are discussed within the respective chapters covering those etiologies. Prior to hysterectomy, however, all patients require Pap smear screening, and abnormal findings require evaluation for cervical cancer prior to surgery (see Chap. 29, Differential Diagnosis and Evaluation of Cervical Lesions). Similarly, women at risk for endometrial cancer and whose indication includes abnormal bleeding typically are also screened before surgery (see Chap. 8, Endometrial Biopsy).

HYSTERECTOMY APPROACH

Hysterectomy may be completed using an abdominal, vaginal, or laparoscopic approach, and selection is influenced by many factors. For example, physical properties of the uterus and pelvis, surgical indications, presence or absence of adnexal pathology, surgical risks, costs, hospitalization and recovery length, and anticipated postoperative quality of life are all weighed once hysterectomy is planned. All three approaches are used commonly, and each carries distinct advantages and disadvantages.

Abdominal Hysterectomy

Most uteri in the United States are removed through an abdominal incision. Either a transverse or a vertical incision may be selected depending on the clinical setting (see Sections 41-1, Midline Vertical Incision and Section 41-2, Pfannenstiel Incision) (Farquhar, 2002). Abdominal hysterectomy allows the greatest ability to manipulate pelvic organs and thus is preferred if large pelvic organs or extensive adhesions are anticipated. In addition, an abdominal approach affords access to the ovaries if oophorectomy is desired, to the space of Retzius when concurrent urogynecologic procedures are planned, or to the upper abdomen for cancer staging. Abdominal hysterectomy typically requires less operating time than laparoscopic hysterectomy and requires no advanced laparoscopic instrumentation or expertise (Falcone, 1999).

However, abdominal hysterectomy is associated with longer patient recovery and hospital stays, increased incisional pain, and greater risk of postoperative febrile morbidity and wound infection (Johns, 1995; Johnson, 2005; Marana, 1999). Additionally, compared with a vaginal approach, abdominal hysterectomy is associated with greater risk of transfusion and ureteral injury but lower rates of postoperative bleeding and bladder injury (Harris, 1996).

Vaginal Hysterectomy

This approach usually is chosen by surgeons if pelvic organs are small, extensive adhesions are not anticipated, no significant

adnexal pathology is expected, and some degree of pelvic organ prolapse is present. When this approach is compared with abdominal hysterectomy, women more often benefit from faster recovery and from reduced hospital stays, costs, and postoperative pain.

Laparoscopic Hysterectomy

This approach typically is selected for women if pelvic organs are small, extensive adhesions are not expected, uterine descensus is poor, and surgeons are skilled in laparoscopic techniques. Although patient recovery, hospital stays, and postoperative pain scores are comparable with those of vaginal hysterectomy, this approach allows greater visualization and access to the abdomen and pelvis. This may be advantageous if oophorectomy is planned or if bleeding or minor adhesive disease is encountered. However, laparoscopy typically requires longer operating times and more expensive equipment. In addition, it has been associated with greater rates of ureteral injury (as high as 14 percent) than either abdominal (0.4 percent) or vaginal hysterectomy (0.2 percent) (Harkki-Siren, 1997a). Laparoscopically assisted vaginal hysterectomy may be considered in those cases in which one or more factors are amenable to laparoscopic manipulation and thus, once corrected, allow hysterectomy to be completed vaginally.

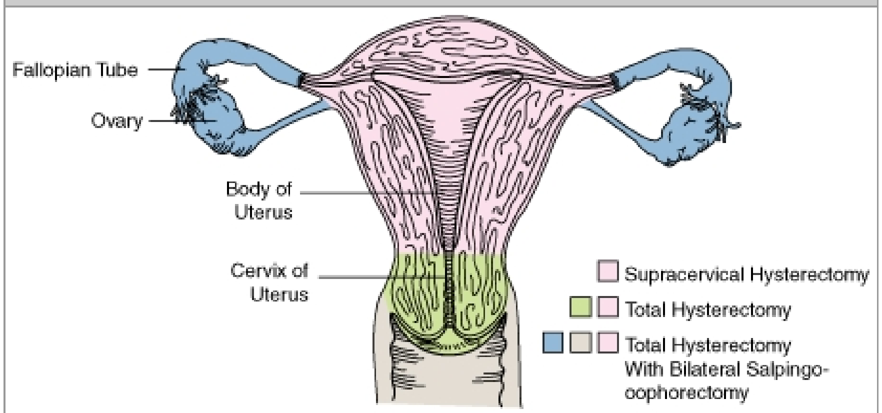
Approach Selection

In sum, if all factors are equal, vaginal hysterectomy should be considered. However, when large pelvic organs, risk of associated malignancy, extensive adhesions, or poor uterine descensus is present, either abdominal or laparoscopic hysterectomy may be required. Of note, surgical expertise is factored into the decision and heavily dictates the approach selected.

Total versus Supracervical Hysterectomy

Prior to hysterectomy, the decision to remove the cervix concurrently is typically discussed with the patient. Hysterectomy may include removal of the uterus and cervix, termed *total hysterectomy,* or may involve only the uterine corpus, called *supracervical hysterectomy* (Fig. 41-19.1). The term s*ubtotal hysterectomy* refers to the supracervical type but is not preferred usage.

FIGURE 41-19.1



Source: Schorge JO, Schaffer JI, Halvorson LM, Hoffman BL, Bradshaw KD, Cunningham FG: *Williams Gynecology*: http://www.accessmedicine.com

Hysterectomy classification.

During the latter half of the twentieth century, most hysterectomies performed were total hysterectomies. The supracervical technique was reserved for patients in whom excision of the cervix risked increased bleeding, surrounding organ damage, or increased operating time.

However, suggested improvement in urinary symptoms and preservation of sexual function have been attributed to cervical conservation, and a trend began in the 1990s toward supracervical hysterectomy (Kilkku, 1983, 1985). Proponents suggest that the cervix provides an important stabilizing function for pelvic support and that the Frankenhauser nerve plexus can be disrupted during total hysterectomy, causing bladder, bowel, or sexual dysfunction. Additionally, advocates argue that this approach decreases surrounding pelvic organ injury and operating times, especially during a laparoscopic approach to hysterectomy

(Baggish, 2005).

Randomized studies, however, have failed to support differences in sexual or urinary function following total abdominal or supracervical hysterectomy (Gimbel, 2005a; Kupperman, 2004; Roussis, 2004; Thakar, 2002). In addition, Learman and co-workers (2003) found no statistically significant differences between the two in surgical complications and clinical outcomes during 2 years of surveillance. In addition, chronic bleeding may follow supracervical hysterectomy. Between 10 and 20 percent of women still will note vaginal bleeding, presumably from retained isthmic endometrium following hysterectomy. Most of these cases end in trachelectomy (Section 41-23, Trachelectomy) (Gimbel, 2005b; Okaro, 2001). Procedures that ablate or core out the endocervical canal may help to prevent this complication (Ewen, 1994; Jenkins, 2004).

Critics of supracervical hysterectomy also have noted the persistent risk for cancer in the conserved stump. However, the risk for cervical cancer in these women is comparable with that in those without hysterectomy, and the prognosis for cervical stump cancer mirrors that in those with a uterus (Hannoun-Levi, 1997; Hellstrom, 2001; Silva, 2004).

In sum, abdominal supracervical hysterectomy offers no distinct advantage over total abdominal hysterectomy, and the risks of persistent bleeding following surgery may deter many women and clinicians from its use.

CONSENT

Hysterectomy for most women is a safe and effective treatment that typically leads to an improved postoperative quality of life and psychological outcome (Hartmann, 2004; Thakar, 2004). However, pelvic organs may be injured during surgery. Vascular, bladder, and ureteral injury are cited most commonly. Accordingly, risks of blood loss and transfusion usually are discussed with a patient before surgery.

Concurrent Bilateral Oophorectomy

Hysterectomy is performed frequently with other surgical procedures. Pelvic reconstructive surgeries and bilateral salpingo-oophorectomy are among the most common.

Ovaries are removed prophylactically in approximately half of hysterectomy cases performed for benign indications. In women younger than 40 years, ovaries typically are conserved because the number of years of expected hormone production is great. In those older than 50 years, bilateral oophorectomy is typical. However, for those in their forties, the decision to remove ovaries prophylactically is controversial.

Proponents of prophylactic oophorectomy argue that the procedure eliminates future ovarian cancer risk and is estimated to prevent 1,000 new cases of ovarian cancer each year (American College of Obstetricians and Gynecologists, 1999). Secondly, the duration of significant ovarian estrogen production following hysterectomy for many is shortened. For example, Siddle and co-workers (1987) noted the mean age of ovarian failure in a group undergoing hysterectomy was 45 years. This was significantly lower than the mean age of 49 years in a control group not receiving surgery. In addition, women with retained ovaries may require future surgery for subsequent benign ovarian disease, and this risk ranges from 1 to 5 percent (Bukovsky, 1988; Zalel, 1997).

However, in those declining oophorectomy, the risk for ovarian cancer still is decreased by 40 to 50 percent by hysterectomy alone (Chiaffarino, 2005; Green, 1997). Additional disadvantages to oophorectomy include long-term effects of hypoestrogenism, such as risks for osteoporosis and coronary artery disease. Parker and colleagues (2005) noted an increased rate of survival to 80 years in women after hysterectomy at ages 50 to 54 years with ovarian conservation (62 percent) compared with those electing oophorectomy without estrogen-replacement therapy (ERT) (54 percent). Although these rates became nearly equal in those electing oophorectomy and then receiving postoperative ERT, concerns regarding ERT compliance have been noted (see Chap. 22) (Speroff, 1991). Castelo-Branco and co-workers (1999) found that after 5 years following hysterectomy and oophorectomy, only a third of women still continued their ERT. Most stopped because of cancer concerns.

In addition to the loss of estrogen, ovarian androgen production is lost. However, its importance in later life has not been entirely delineated (Olive, 2005).

PATIENT PREPARATION

Postoperative vaginal cuff cellulitis and urinary tract infection are risks following hysterectomy. For this reason, patients typically receive antibiotic prophylaxis with either a first- or second-generation cephalosporin (Hemsell, 2001). Alternatively, metronidazole or tinidazole may be used (see Table 39-7). The risk of bowel injury with hysterectomy is low. Accordingly, for most women, an enema administered prior to surgery to evacuate the rectum is sufficient. A more extensive preparation may be indicated if extensive pelvic adhesive disease is anticipated.

Intraoperative

Surgical Steps

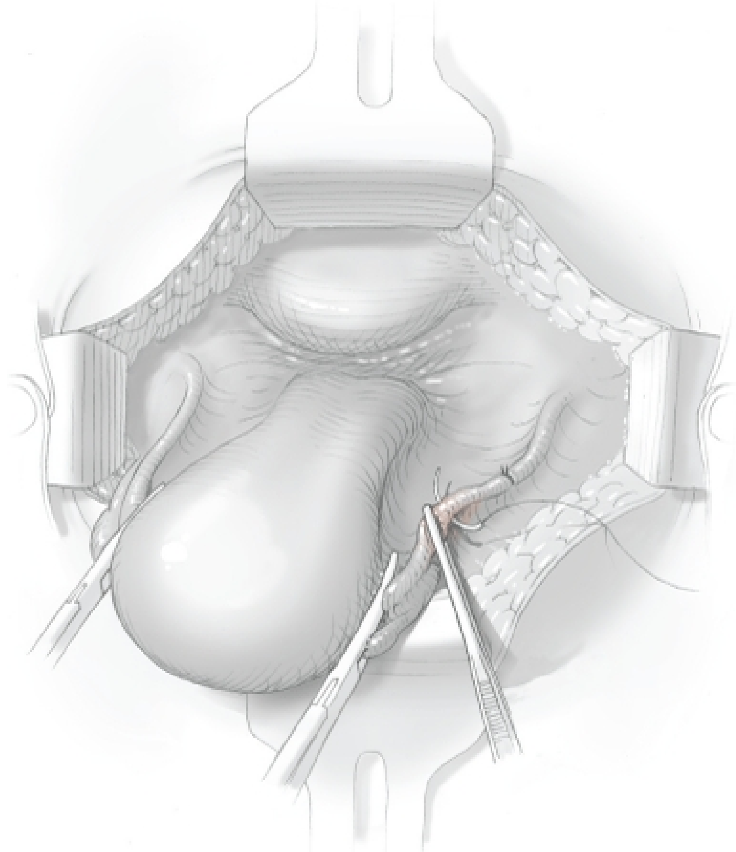
1. **Anesthesia and Patient Positioning.** Abdominal hysterectomy typically is performed under general anesthesia, although regional anesthesia also may be used. The patient is positioned supine, a Foley catheter is placed, and the abdomen and vagina are prepped for surgery.

2. **Abdominal Entry.** Either a transverse or a vertical incision may be used for hysterectomy, and clinical factors influence selection (see Sections 41-1, Midline Vertical Incision and 41-2, Pfannenstiel Incision).

3. **Exposure.** Following entry into the abdomen, a self-retaining retractor such as an O'Connor-O'Sullivan or Balfour retractor is placed. The pelvis and abdomen are explored visually and manually, and the bowel is packed from the operating field. The uterus is grasped and elevated from the pelvis. If extensive adhesions are present, normal anatomic relationships are restored to aid surgery. Hysterectomy may be performed by one surgeon, but commonly two surgeons are present, with each typically operating on his or her side of the uterus.

4. **Round Ligament Transection.** Curved Kelly clamps are placed bilaterally across each fallopian tube and utero-ovarian ligament immediately lateral to the uterus (Fig. 41-19.2). Attention is directed to one of the round ligaments, where midsection division is planned. A transfixing suture using 0-gauge delayed-absorbable suture is placed about 1 cm proximally and another suture 1 cm distally to this planned division. These sutures are held by hemostats and are directed upward and outward to create tension along the interposed segment of round ligament. The round ligament is cut, and this incision is directed inferiorly into the first 1 to 2 cm of the broad ligament.

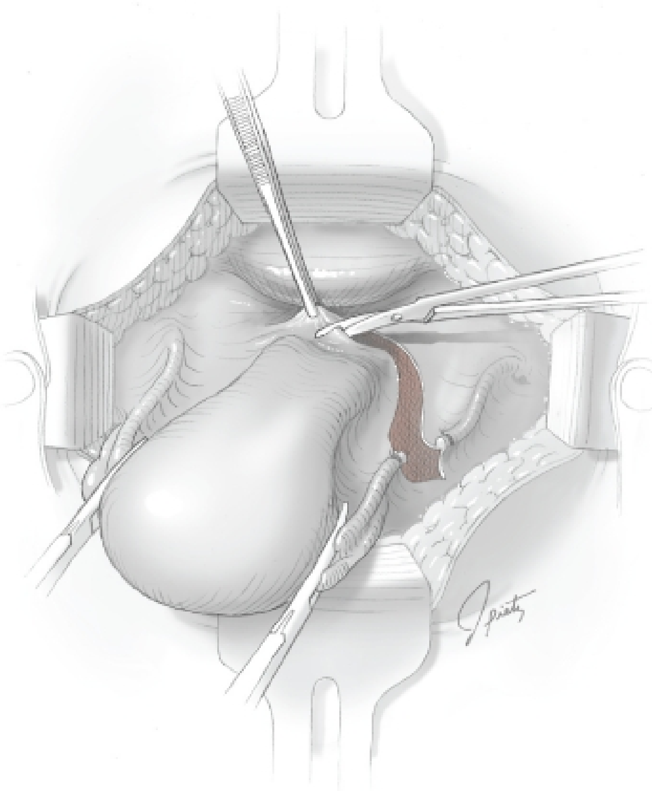
FIGURE 41-19.2



Round ligament transection.

5. **Broad Ligament Leaves.** With this action, the broad ligament separates to create anterior and posterior leaves, and between them, gauzy areolar connective tissue is seen. The leading medial and lateral edges of the anterior leaf are grasped with smooth atraumatic forceps. Tension on these edges is directed upward and outward. The tented anterior leaf then is incised sharply, with the line of incision curving inferiorly and medially to the level of the vesicouterine fold (Fig. 41-19.3). Similarly, the posterior leaf of the broad ligament is opened. The incision extends inferomedially toward the uterosacral ligaments. At this point, it is advantageous to identify the ureters, particularly before any tissue clamps are placed.

FIGURE 41-19.3



Source: Schorge JO, Schaffer JI, Halvorson LM, Hoffman BL, Bradshaw KD, Cunningham FG: *Williams Gynecology*: http://www.accessmedicine.com

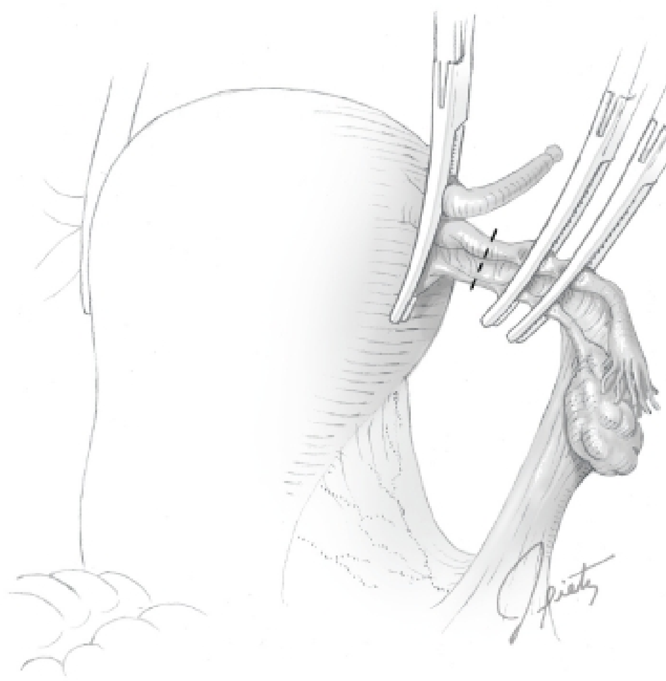
Anterior leaf opened.

6. **Ovarian Conservation.** Attention now may be directed to the adnexa. With the leaves of the broad ligament now open, if adnexa are to be preserved, the surgeon's index finger can be curved under the fallopian tube and utero-ovarian ligament (Fig. 41-19.4).

   One Kelly clamp was already placed at the beginning of surgery across the fallopian tube and utero-ovarian ligament and lies proximal to the surgeon's finger. Two Heaney or other appropriate clamps then are placed lateral to the finger, with each clamp arc directed toward the uterus (Fig. 41-19.4).

   The surgeon's finger is removed, and the intervening segment of fallopian tube and utero-ovarian ligament is incised between the medial Heaney clamp and Kelly clamp. A free tie of 0-gauge delayed-absorbable suture is placed around the more lateral of the two Heaney clamps. As the knot of this suture is tied securely, the lateral of these two clamps is removed. A transfixing suture then is placed around the remaining Heaney clamp. This suture is placed above and distal to the first free tie. As the knot is cinched in place, the Heaney clamp is removed. The Kelly clamp is left in place. The adnexa is now freed from the uterus.

FIGURE 41-19.4



Source: Schorge JO, Schaffer JI, Halvorson LM, Hoffman BL, Bradshaw KD, Cunningham FG: *Williams Gynecology*: http://www.accessmedicine.com

Ovarian conservation.

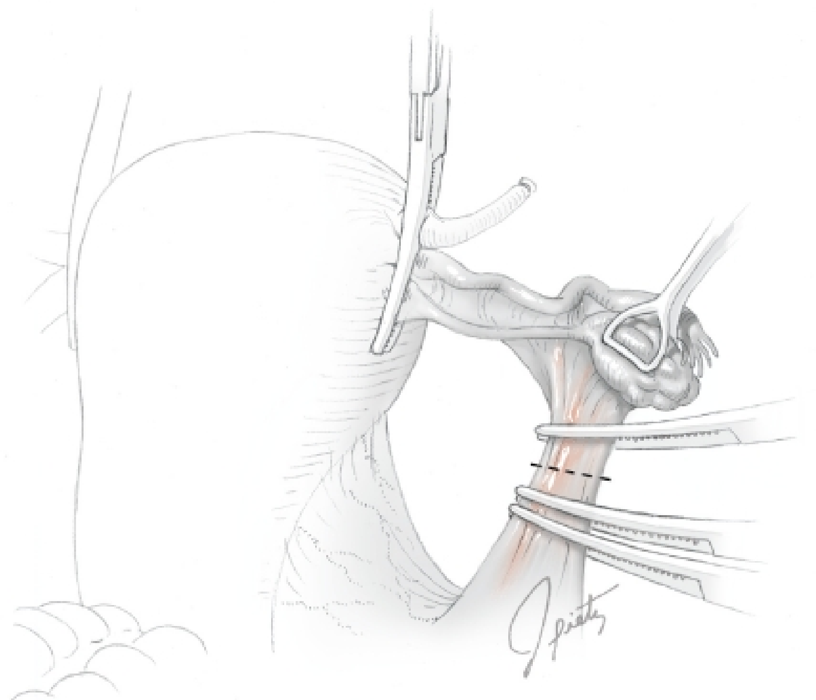
7. **Oophorectomy.** If the adnexa are to be removed, the tube and ovary are grasped with a Babcock clamp and elevated away from the infundibulopelvic (IP) ligament (Fig. 41-19.5). The peritoneum lateral to this ligament is incised, and this incision is extended cephalad and laterally. The peritoneum medial to the IP ligament was incised earlier as part of the posterior leaf of the broad ligament.

   With the IP ligament now isolated, curved Heaney clamps can be placed around this ligament. As with the utero-ovarian ligaments, two clamps are placed proximal to the planned site of incision, and one clamp is placed distally. All arcs of these curved clamps are directed toward the site of planned incision.

   Once the clamps have been placed, the IP ligament is transected. Ligation of the IP is carried out as in step 9. A free-tie 0-gauge delayed-absorbable suture is placed around the more proximal of the two Heaney clamps. As the knot of this suture is tied securely, the proximal clamp is removed. A transfixing suture then is placed around the remaining Heaney clamp. This suture is placed above and distal to the first free tie. As the knot is cinched in place, the remaining Heaney clamp is removed.

   The adnexum is now freed from the pelvic sidewall and its increased mobility may obstruct surgery. For this reason, the adnexa can be tied to the Kelly clamp located on the utero-ovarian ligament.

FIGURE 41-19.5



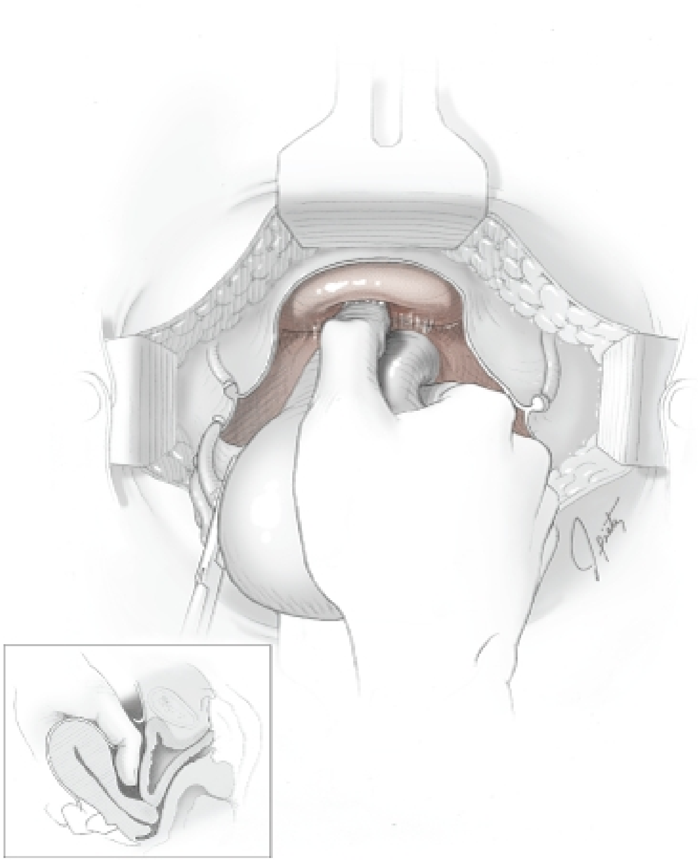
Source: Schorge JO, Schaffer JI, Halvorson LM, Hoffman BL, Bradshaw KD, Cunningham FG: *Williams Gynecology*: http://www.accessmedicine.com

Oophorectomy.

8. **Bladder Flap.** Attention next is turned to the bladder. The peritoneum that connects the superior edge of the bladder to the uterine isthmus was cut when the anterior leaf of the broad ligament was opened. Only loose areolar connective tissue joins the posterior surface of the bladder and anterior surface of the uterine isthmus and cervix. As a result, a hand can be wrapped around the uterus and a thumb used to exert gentle pressure under the bladder and against the uterine surface inferiorly toward the vagina. Countertension on the uterus is created by pulling upward on the Kelly clamps previously placed at the cornua. Similarly, a sponge stick can be used to create this pressure. In this fashion, the bladder can be separated from the underlying lower uterine segment and cervix (Fig. 41-19.6).

   Alternatively, some patients may have scar tissue connecting the posterior surface of the bladder to the anterior uterine surface. In this instance, sharp dissection with Metzenbaum scissors may be required to detach the bladder from the isthmus and cervix.

FIGURE 41-19.6



Source: Schorge JO, Schaffer JI, Halvorson LM, Hoffman BL, Bradshaw KD, Cunningham FG: *Williams Gynecology*: http://www.accessmedicine.com

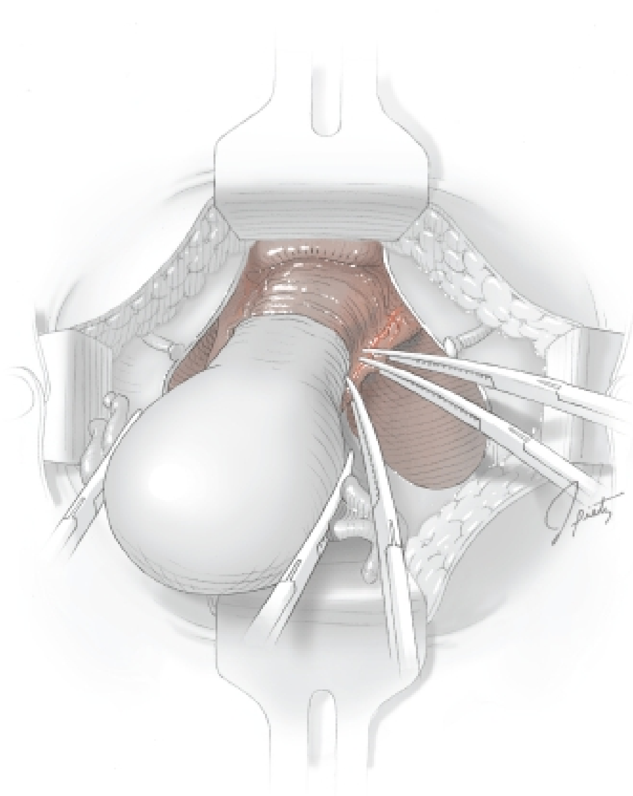
Bladder flap dissection.

9. **Uterine Arteries.** Next, the uterine arteries are identified along the lateral aspects of the uterus at the level of the isthmus. Excess connective tissue surrounds these vessels and is grasped with fine, smooth forceps. The connective tissue is retracted gently laterally and away from the vessels. Curved Metzenbaum scissors incise this tissue beginning superiorly and proceeding inferiorly. The technique is often referred to as *skeletonizing* and removes excess tissue from around vessels prior to their ligation.

   Two curved Heaney clamps are placed on the uterine vessels inferiorly to the planned site of vessel transection. These clamp tips are placed horizontally across the vertical axis of the uterine vessels (Fig. 41-19.7). A third curved clamp is placed above the planned incision. Its tip crosses the vessels at an approximate 45-degree angle. The uterine vessels are then sharply transected.

   A simple stitch of 0-gauge delayed-absorbable suture is placed below the lowest clamp's tip, and the suture ends are wrapped to the heel of the clamp. As the knot is cinched, the middle of the three clamps is opened and then closed immediately. The lowest of the three then is removed. A simple stitch then is placed above the first suture and below the middle clamp. As the knot is cinched, this clamp is removed. The upper clamp is left in place to prevent vessel bleeding from the rich collateral uterine circulation.

FIGURE 41-19.7



Source: Schorge JO, Schaffer JI, Halvorson LM, Hoffman BL, Bradshaw KD, Cunningham FG: *Williams Gynecology*: http://www.accessmedicine.com

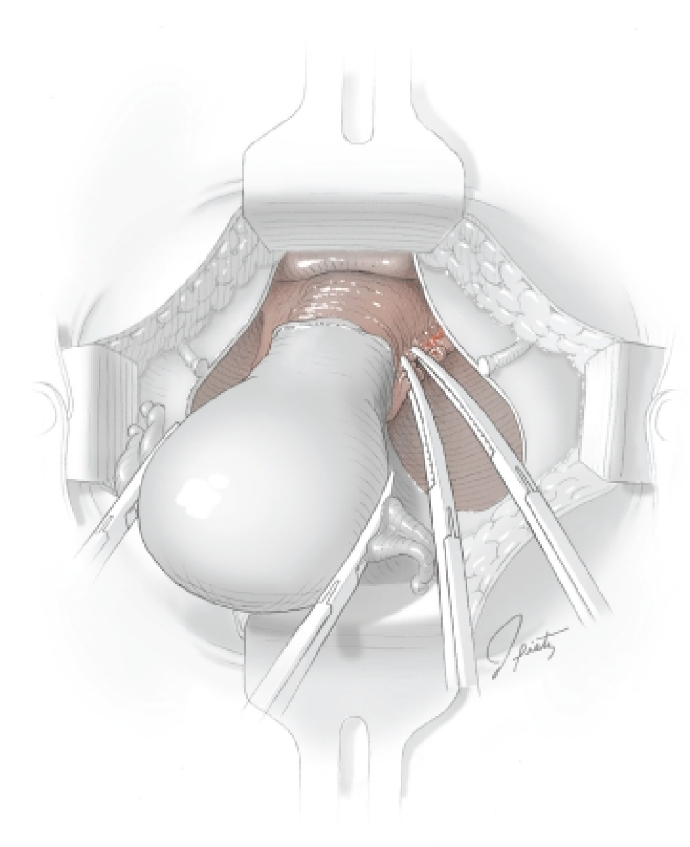
Uterine artery ligation.

10. **Fundal Amputation.** After bilateral ligation of the uterine arteries, if the uterus is large and bulky, the uterine fundus may be severed sharply from the isthmus and cervix. After removal of the corpus, a single-toothed Kocher clamps can be placed on the anterior and posterior walls of the uterine isthmus to elevate the cervix.

11. **Cardinal Ligament Incision.** These ligaments lie lateral to the uterus and are inferior to the uterine vessels. A straight Heaney clamp is used to clamp the cardinal ligament (Fig. 41-19.8). As the Heaney clamp initially grasps the ligament, it is oriented parallel to the lateral side of the uterus. As the clamp is slowly closed, it is angled approximately 45 degrees from the vertical axis of the uterus. A second clamp may be placed medial to the first. A scalpel is used to transect the portion of the cardinal ligament held between the clamps. A transfixing suture of 0-gauge delayed-absorbable suture is placed below the clamp, the knot is cinched, and the clamp removed. The medial Heaney clamp, if used, is left in place to prevent bleeding.

    Because of the vertical length and vascularity of the cardinal ligament, it may be necessary to repeat step 11. In this manner, the cardinal ligament is ligated, from its superior to inferior extent, using a series of clamping and suturing events down the lateral aspect of the uterus and lateral aspect of the upper vaginal vault.

FIGURE 41-19.8

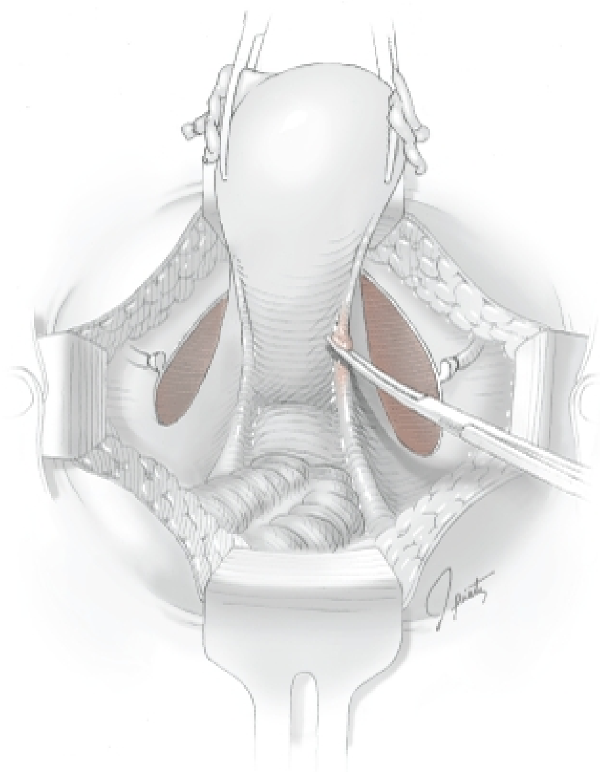


Source: Schorge JO, Schaffer JI, Halvorson LM, Hoffman BL, Bradshaw KD, Cunningham FG: *Williams Gynecology*: http://www.accessmedicine.com

Cardinal ligament transection.

12. **Uterosacral Ligament Transection.** At this point, attention is directed to the posterior aspect of the uterus and to the uterosacral ligaments (Fig. 41-19.9). Upward traction is exerted by the Kelly clamps placed at the uterine cornua. Each ligament is grasped with a straight Heaney clamp close to its uterine attachment. Importantly, because of the close proximity of the ureter, these clamps are placed as close to the uterus as possible. The ligament is severed medial to the clamp, a transfixing suture is placed, and the clamp is removed.

FIGURE 41-19.9

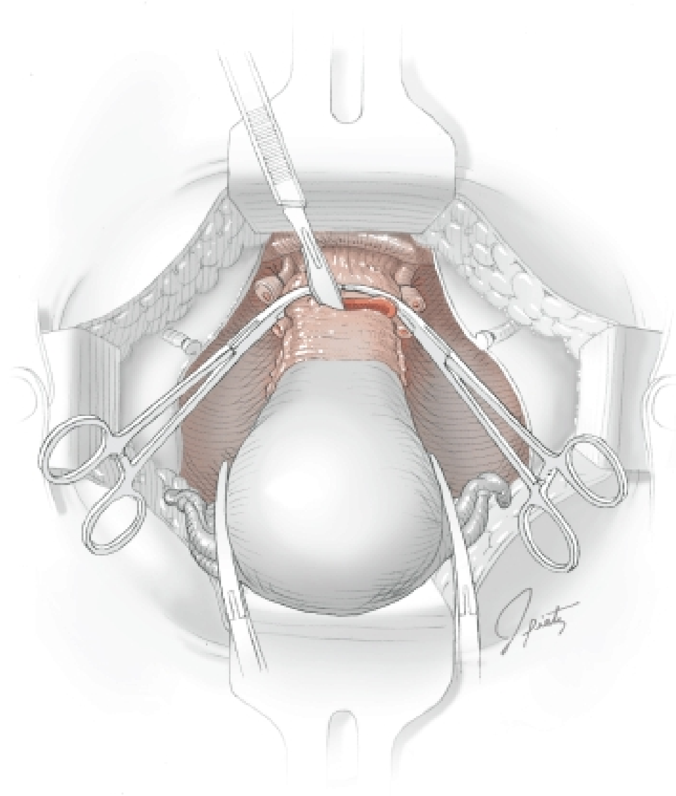


Source: Schorge JO, Schaffer JI, Halvorson LM, Hoffman BL, Bradshaw KD, Cunningham FG: *Williams Gynecology*: http://www.accessmedicine.com

Uterosacral ligament transection.

13. **Vaginal Entry.** At this point the surgeon's hand may palpate through the anterior and posterior vaginal walls to identify the most inferior level of the cervix. Here, curved Heaney clamps are used grasp and bring together the anterior and posterior vaginal walls at the point just below the cervix (Fig. 41-19.10).

FIGURE 41-19.10



Source: Schorge JO, Schaffer JI, Halvorson LM, Hoffman BL, Bradshaw KD, Cunningham FG: *Williams Gynecology*: http://www.accessmedicine.com

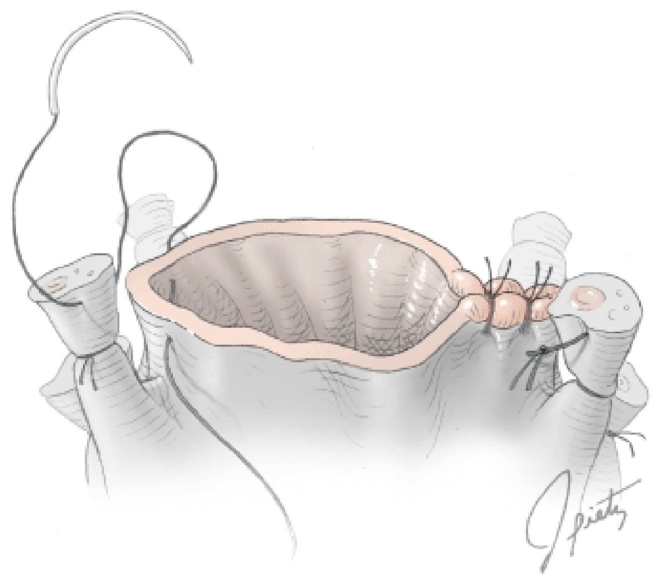
Uterine excision.

14. **Removal of the Uterus.** The vaginal tissue above these clamps then is incised, and vaginal tissue extending between these two clamps then is cut with knife or Mayo scissors. This procedure frees the uterus from the pelvis. Transfixing sutures are placed below the Heaney clamps, and the clamps are removed.

15. **Vaginal Cuff Closure.** A long length of 0-gauge delayed-absorbable suture is used to join together the uterosacral ligament pedicle and the vaginal apex pedicle on the right (Fig. 41-19.11). A knot will cinch these together. A similar bundle is tied together on the left of the vaginal apex. This bilateral joining of the vaginal apex to the uterosacral ligaments helps to prevent vaginal cuff prolapse following surgery.

    The short ends of the sutures used to bind these pedicles are grasped with hemostats. These hemostat are directed upward and laterally to create tension along the vaginal cuff. The anterior cut edge of the vagina then is reapproximated to the posterior cut vaginal edge with several figure-of-eight sutures using 0-gauge delayed-absorbable suture. The lateral elevating sutures then are cut.

FIGURE 41-19.11



Source: Schorge JO, Schaffer JI, Halvorson LM, Hoffman BL, Bradshaw KD, Cunningham FG: *Williams Gynecology*: http://www.accessmedicine.com

Vaginal cuff closure.

16. **Wound Closure.** The abdominal incision is closed as described in Sections 41-1, Midline Vertical Incision and 41-2, Pfannenstiel Incision.

Postoperative

Following abdominal hysterectomy, postoperative care follows that for any major abdominal surgery. Hospitalization typically varies from 1 to 4 days, and return of normal bowel function and febrile morbidity usually dictate this course. Postoperative activity in general can be individualized, although intercourse usually is delayed until 4 to 6 weeks after surgery to allow time for vaginal cuff healing.

Febrile morbidity is common following abdominal hysterectomy and exceeds that seen with vaginal or laparoscopic approaches (Peifert, 2004). Frequently, fever is unexplained, but pelvic infections are common. Additionally, abdominal wound infection, urinary tract infection, and pneumonia should be considered (see Fig. 39-6). Because of the high rate of unexplained fever, which resolves spontaneously, observation for 24 to 48 hours for mild temperature elevations is reasonable. Alternatively, in those at higher risk of infection, a second-generation cephalosporin may be administered. Additional testing, including transvaginal sonography or computed tomographic scanning, may be indicated if a pelvic hematoma or abscess is suspected.

41-20 VAGINAL HYSTERECTOMY

In general, vaginal hysterectomy offers short patient recovery, operating times, and hospitalization as well as decreased surgical morbidity. Ideally, it is used when pelvic organs are small, some degree of uterine descensus is present, and access to the upper abdomen is not required. Similarly, this approach typically is not selected in those with a contracted pelvis or significant pelvic adhesions.

Preoperative

Patient evaluation, consent, and patient preparation are similar to those for abdominal hysterectomy (see Section 41-19, Hysterectomy).

Intraoperative

Surgical Steps

1. **Anesthesia and Patient Positioning.** After adequate general or regional anesthesia is administered, the patient is placed in high or standard dorsal lithotomy position (see Chap. 40, Dorsal Lithotomy). The vagina is surgically prepped, and a Foley catheter is placed. A right-angle or other suitable retractor is placed along the anterior vaginal wall, whereas a weighted vaginal speculum is placed posteriorly.

2. **Vaginal Wall Incision.** A Lahey thyroid clamp is used to grasp both the anterior and posterior cervical lips and close them together. Between 10 and 15 mL of a dilute saline solution containing vasopressin (20 units diluted in 20 mL of saline) or 0.5-percent lidocaine and epinephrine (1:200,000 dilution) is injected circumferentially beneath the mucosa at a level above the cervicovaginal junction but below the inferior margin of the bladder. The margin of the bladder is identified as a crease in the overlying vaginal epithelium. This margin can be accentuated by in-and-out displacement of the cervix (Sheth, 2005). Injection of vasocontrictors decreases bleeding during dissection and aids in defining tissue planes. The vaginal wall above the cervix then is circumcised. To avoid dissection into the cervix, this incision is kept at a depth superficial to the pubocervical fascia.

3. **Anterior Peritoneal Entry.** The anterior vaginal wall is grasped and elevated with an Allis clamp. Additional, tension is created by outward traction on the Lahey thyroid clamp. This traction will reveal fibrous bands connecting the bladder and cervix. With surgical gauze covering the index finger, the surgeon pushes downward and cephalad against the cervix to bluntly dissect through these fibers and move the bladder anteriorly. This motion is continued until the vesicouterine fold is reached. In patients in whom these cervicovesical fibrous bands are dense, sharp dissection may be required to avoid blunt cystotomy by the surgeons's finger (Fig. 41-20.1).

   The vesicouterine fold can be seen as a transverse white line across the anterior cervix. Palpation reveals two thin smooth layers of peritoneum slipping against one another (Fig. 41-20.2). The vesicouterine fold is grasped and elevated to place this peritoneal layer on tension. The peritoneum then is incised (Fig. 41-20.3). An index finger explores the opening to confirm peritoneal entry and palpate for any unanticipated pathology. The anterior retractor then is repositioned with its distal blade entering the peritoneal cavity and elevating the bladder.

FIGURE 41-20.1

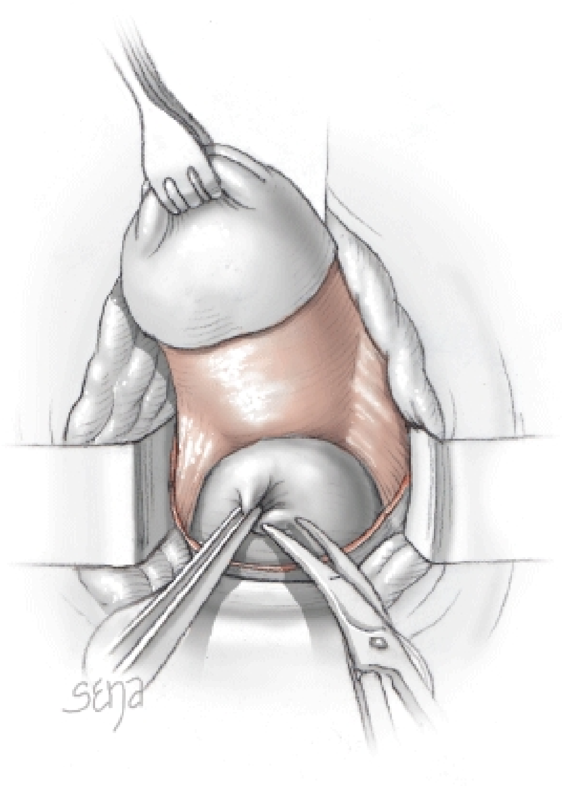
Vesicouterine fold incision.

4. **Posterior Entry.** The Lahey thyroid clamp and cervix are lifted anteriorly to expose the posterior vaginal vault, and an Allis clamp is placed on the incised edge of the posterior vaginal wall. The Allis clamp is pulled downward to create tension across the exposed posterior peritoneum. The posterior vaginal vault is cut with curved Mayo scissors, and the Douglas cul-de-sac is entered (Fig. 41-20.4). The posterior peritoneum is affixed centrally to the posterior vaginal wall incision with a single stitch of delayed-absorbable suture. This approximation will assist with closure of the peritoneum at the procedure's end. The short, weighted vaginal speculum is replaced by one with a longer blade, which enters the cul-de-sac.

FIGURE 41-20.4



Source: Schorge JO, Schaffer JI, Halvorson LM, Hoffman BL, Bradshaw KD, Cunningham FG: *Williams Gynecology*: http://www.accessmedicine.com

Entry into the cul-de-sac of Douglas.

5. **Transection of Uterosacral and Cardinal Ligaments.** Outward traction on the Lahey thyroid clamp pulls the supporting uterine ligaments into view. Such traction on the cervix aids in preventing ureteral injury.

   The uterosacral ligament is identified, clamped with a curved Heaney clamp, transected, and ligated with 0-gauge delayed-absorbable suture using a transfixing stitch (Fig. 41-20.5).

   After ligation of the uterosacral ligaments, the cardinal ligaments similarly are clamped, cut, and sutured (Fig. 41-20.6). When the anterior jaw of the Heaney clamp is positioned around the cardinal ligament, the anterior peritoneal edge is pulled downward and incorporated into the pedicle.

   The uterosacral and cardinal ligaments may be isolated, clamped, and ligated individually or in combination depending on the size of each. Once the knots of these pedicles are secured, the suture ends are not cut but rather are held by hemostats. These will be sutured later to the vaginal cuff to aid in long-term vaginal support.

FIGURE 41-20.5

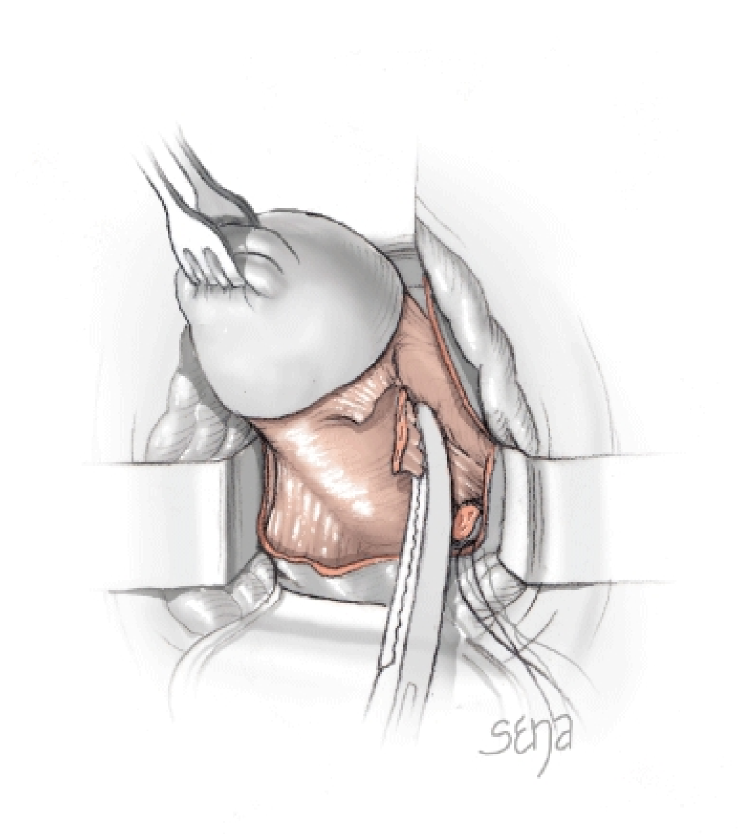
FIGURE 41-20.6



Source: Schorge JO, Schaffer JI, Halvorson LM, Hoffman BL, Bradshaw KD, Cunningham FG: *Williams Gynecology*: http://www.accessmedicine.com

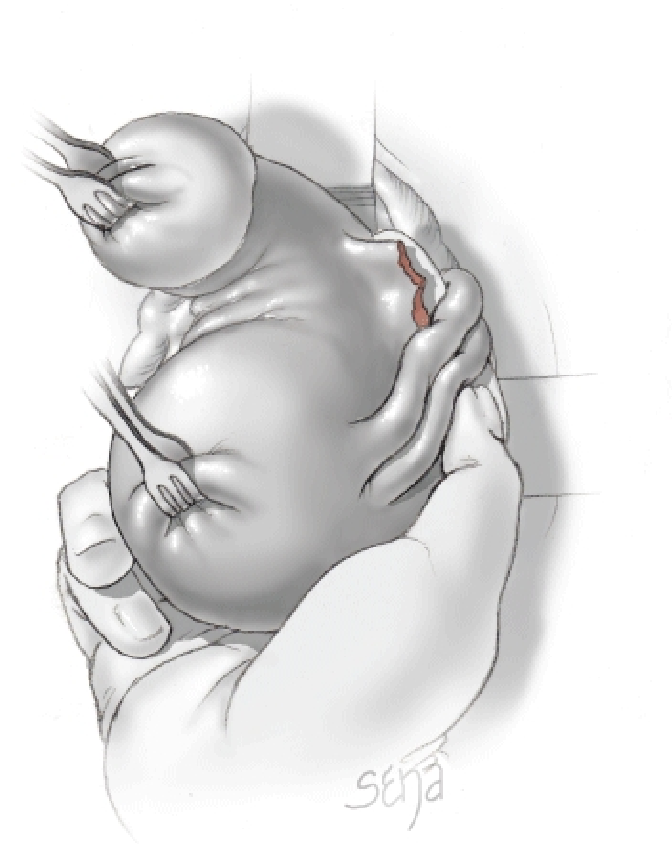
Cardinal ligament transection.

6. **Uterine Arteries.** The uterine arteries are identified and serially clamped with two curved Heaney clamps. A simple suture is placed behind the proximal clamp and is secured as this clamp is removed. A second suture is then placed behind the distal clamp.

7. **Utero-ovarian and Round Ligaments.** If the uterus is small and descensus adequate, two curved Heaney clamps may be placed in tandem across the utero-ovarian and round ligaments and fallopian tubes. Each pedicle is doubly ligated with a simple suture first placed medially. A transfixing stitch is then placed distally and held by hemostat.

   Alternatively, if the uterus is larger, the uterine corpus may be delivered through either the anterior or posterior colpotomy incision to expose these ligaments (Fig. 41-20.7). To deliver the fundus, either fingers or a tenaculum can be used to pull the fundus into the vagina.

FIGURE 41-20.7



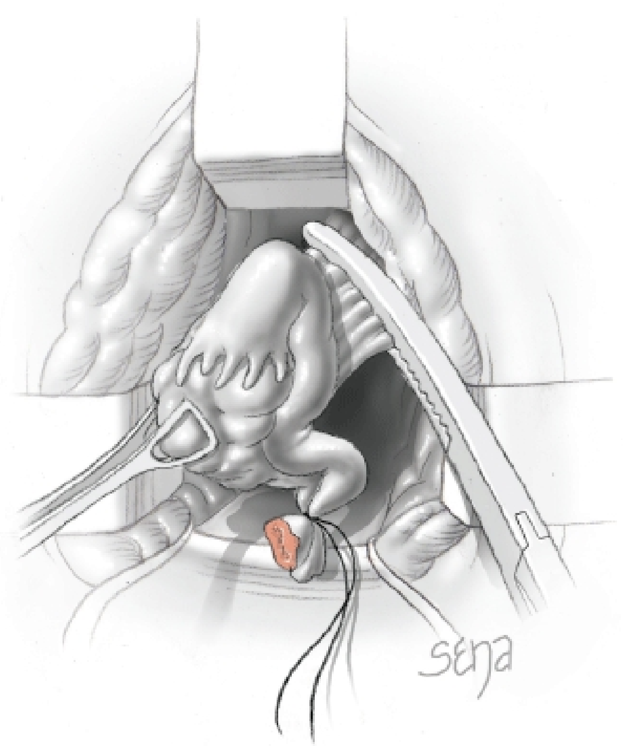
Source: Schorge JO, Schaffer JI, Halvorson LM, Hoffman BL, Bradshaw KD, Cunningham FG: *Williams Gynecology*: http://www.accessmedicine.com

Utero-ovarian and round ligaments transection.

8. **Morcellation.** In some cases, a uterine fundus may be too large to deliver, and debulking of the uterus may be required. This can be done by enucleating individual large leiomyomas or by cervix-to-fundus central coring using scissors or scalpel. Once the bulk has been diminished, Heaney clamps may be placed around the utero-ovarian ligaments as described in step 7.

9. **Oophorectomy.** If removal of the ovaries is desired, the adnexa is grasped with a Babock clamp and gently pulled toward the incision. An index finger is wrapped around the infundibulopelvic (IP) ligament to isolate it from surrounding structures. The IP ligament is clamped and ligated similarly to the utero-ovarian pedicle. The ends of its final transfixing suture are held by hemostat (Fig. 41-20.8).

FIGURE 41-20.8



Oophorectomy.

10. **Evaluation of Hemostasis.** Following removal of the uterus, the surgical pedicles are inspected for bleeding. Electrosurgical coagulation or individual figure-of-eight sutures typically will control bleeding. If hemostasis is adequate, sutures to the IP ligament are cut. At this juncture, if an enterocoele repair is planned, it is performed.

11. **Vaginal Cuff Closure.** The peritoneum is closed in a purse-string manner using 2-0 delayed-absorbable suture. Next, a suspensory suture may be included in which the cardinal or uterosacral or both ligaments are sutured to the lateral vaginal cuff on each side to improve final suspension and support for the vaginal vault (Figs. 41-20.9 and 41-20.10). This is repeated on the left. The vaginal wall incision is closed left to right with interrupted or continuous running sutures of 0-gauge delayed-absorbable material.

Postoperative

In general, patients following vaginal hysterectomy, compared with abdominal hysterectomy, typically have faster return of normal bowel function, easier ambulation, and decreased analgesia requirements. Evaluation and treatment of postoperative complications mirror those for abdominal hysterectomy.

41-21 LAPAROSCOPIC HYSTERECTOMY

Gynecology has fully embraced the laparoscopic approach to surgical procedures, and in the 1990s, a trend toward greater use of this modality for hysterectomy began. Several laparoscopic techniques have been developed for hysterectomy and vary depending on the degree of laparoscopic dissection versus vaginal surgery required to remove the uterus (Garry, 1994). These include

- Diagnostic laparoscopy prior to vaginal hysterectomy (VH)
- Vaginal hysterectomy assisted by laparoscopy; that is, lysis of adhesions and/or excision of endometriosis prior to VH
- Laparoscopically assisted vaginal hysterectomy (LAVH): laparoscopic dissection down to, but not including, uterine artery transection
- Laparoscopic hysterectomy (LH): laparoscopic dissection, including uterine artery transection
- Total laparoscopic hysterectomy (TLH): complete laparoscopic excision of the uterus

Most hysterectomies performed currently in the United States are either laparoscopically assisted vaginal hysterectomy (LAVH) or laparoscopic hysterectomy (LH).

Intraoperative

INSTRUMENTS

A number of instruments have been developed to assist the laparoscopic surgeon and to provide functions similar to those afforded by laparotomic tools. Vessel occlusion is an important component of any hysterectomy. For this, several different instruments have been used and include monopolar or bipolar grasping forceps, harmonic scalpel, stapling devices, and extracorporeal suturing. Of these modalities, the harmonic scalpel has gained increasing popularity because of its ability to cut cleanly with minimal smoke plume and little surrounding thermal tissue damage (see Chap. 40, Ultrasonic Scalpel).

Surgical Steps

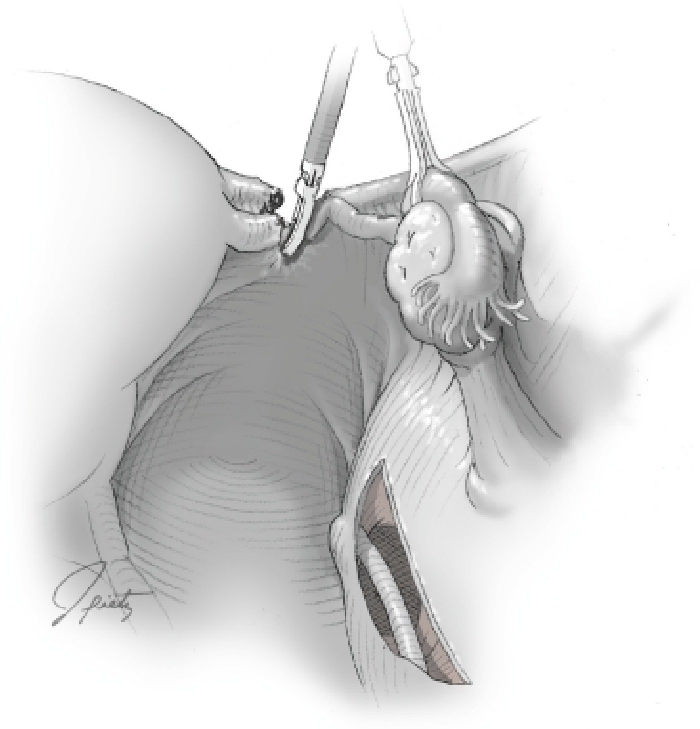
1. **Anesthesia and Patient Positioning.** For most women, these procedures are performed as an inpatient procedure under general or regional anesthesia. The patient is placed in a low dorsal lithotomy position, the vagina is surgically prepped, and a Foley catheter is placed.

2. **Initial Steps.** The introductory steps for LH mirror that for other laparoscopic procedures (see Laparoscopy). The number of trocars and their caliber may vary, but in general, LH requires a 10- to 12-mm trocar placed below the umbilicus and two or three secondary access trocars placed through the lower abdominal wall. Two trocars are placed beyond the lateral borders of the rectus abdominis muscle, whereas a third may be positioned centrally and cephalad to the uterine fundus.

   The patient is placed in Trendelenburg position to aid displacement of the bowel from the operating field. A blunt probe also is often helpful with bowel displacement. The pelvis and abdomen are inspected, and adhesions are lysed to restore normal anatomy.

3. **Ureter Identification.** Irrigating fluids and CO_2 used for insufflation can with time create edema of the peritoneum and hinder visualization of structures beneath it. For this reason, the ureters should be identified early. In many cases, the ureters can be visualized without difficulty beneath the pelvic peritoneum. However, it is sometimes necessary to open the peritoneum for identification. In such situations, the peritoneum medial to the infundibulopelvic (IP) ligament and overlying the ureter is grasped and tented using atraumatic forceps and incised with scissors. An irrigating probe is used to force water beneath and elevate the peritoneum for easier incision. The opening in the peritoneum then is extended caudally and cephalad along the length of the ureter. Through this peritoneal window, the ureter is identified (Fig. 41-21.1) (Parker, 2004).

FIGURE 41-21.1



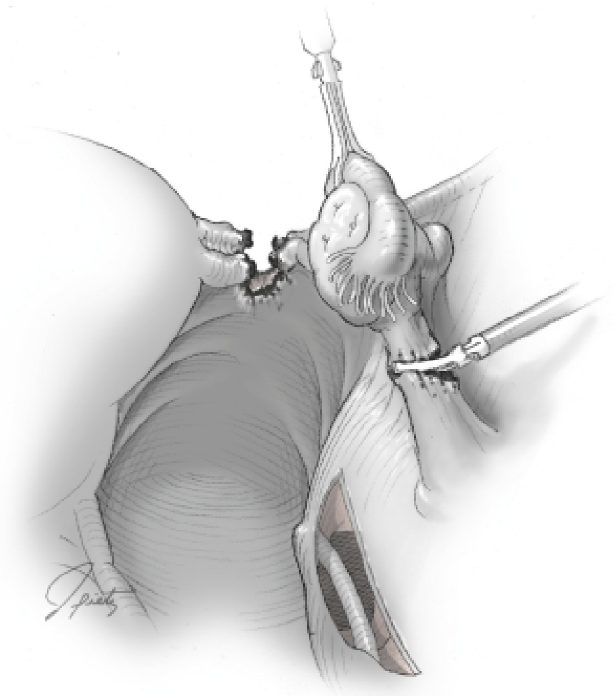
Source: Schorge JO, Schaffer JI, Halvorson LM, Hoffman BL, Bradshaw KD, Cunningham FG: *Williams Gynecology*: http://www.accessmedicine.com

Ureter identification. Fallopian tube and round ligament transection.

4. **Ovarian Conservation.** If preservation of the ovaries is planned, proximal portions of the round ligament, fallopian tube, and utero-ovarian ligament are desiccated and transected (Fig. 41-21.1).

5. **Oophorectomy.** If removal of the ovaries is desired, the infundibulopelvic (IP) ligament is grasped and pulled up and away from retroperitoneal structures. It is desiccated or stapled, and then divided (Fig. 41-21.2). The proximal portions of the round ligament, fallopian tube, and utero-ovarian ligament are desiccated and transected. The broad ligament beneath the adnexa is then sharply incised to free the adnexa.

FIGURE 41-21.2



Source: Schorge JO, Schaffer JI, Halvorson LM, Hoffman BL, Bradshaw KD, Cunningham FG: *Williams Gynecology*: http://www.accessmedicine.com

Infundibulopelvic ligament transection.

6. **Broad Ligament Incision.** With hysterectomy, incisions in the right and left anterior leaves of the broad ligament are directed caudally and centrally to meet in the midline above the vesicouterine fold. The posterior leaf requires incision caudally to the level of the uterosacral ligament. The loose areolar tissue separating the anterior and posterior leaves is dissected as well.

7. **Bladder Flap Development.** The vesicouterine edge is grasped with atraumatic forceps and elevated. This exposes connective tissue between the bladder and underlying uterus. This tissue then is dissected. Of the hysterectomy types, LH has the highest risk of bladder injury, and injury occurs most frequently to the dome during this sharp or blunt dissection (Harkki, 2001).

8. **Uterine Artery Transection.** After the uterine arteries are identified, the areolar connective tissue surrounding them is grasped, placed on tension, and incised. This skeletonizing of the vessels leads to superior occlusion of the uterine artery and vein. The arteries then are dessicated and transected. Alternatively, surgeons may elect to terminate the laparoscopic portion prior to uterine artery transection and complete artery ligation from a vaginal approach (LAVH).

   The ureters are also at greater risk during LH compared with other hysterectomy approaches (Harkki-Siren, 1998). Kuno and colleagues (1998) evaluated the use of ureteral catheterization to prevent such injury but found no benefit.

9. **Vaginal Hysterectomy.** With LH, after the uterine arteries are transected, the surgical approach is converted to that for

vaginal hysterectomy and completed as outlined in Section 41-20, Vaginal Hysterectomy. In this transition, the patient is repositioned from low dorsal lithotomy to standard or high lithotomy positions.

10. **Abdominal Inspection.** After vaginal completion of the hysterectomy, attention is redirected to laparoscopic inspection of the pelvis for signs of bleeding. The pelvis is irrigated and suctioned free of blood. The laparoscopic procedure is terminated as outlined in Laparoscopy.

Postoperative

Following LH, patient recovery mirrors that for vaginal hysterectomy.

41-22 LAPAROSCOPIC SUPRACERVICAL HYSTERECTOMY

Laparoscopic supracervial hysterectomy (LSH) differs from total laparoscopic hysterectomy (TLH) in that the uterine corpus is amputated, but the cervix remains. Once freed, the corpus is either delivered through a colpotomy incision or more commonly, is morcellated and removed through laparoscopic incisions. Different names for the procedure reflect minor variations in technique and include

- CISHâ€”cervical intrafacial Semm hysterectomy
- CASHâ€”classic abdominal Semm hysterecomy
- LASHâ€”laparoscopic supracervical hysterectomy
- SPLASHâ€”single-puncture laparoscopic supracervical hysterectomy.

The LASH technique is described below.

Intraoperative

INSTRUMENTS

During cervical amputation, blunt scissors, harmonic scalpel, morcellator knife, laser, or monopolar scissors may be used to excise the corpus. Of these modalities, the harmonic scalpel is favored because it offers the cleanest separation lines, smallest cautery plume, and least thermal damage to surrounding tissues.

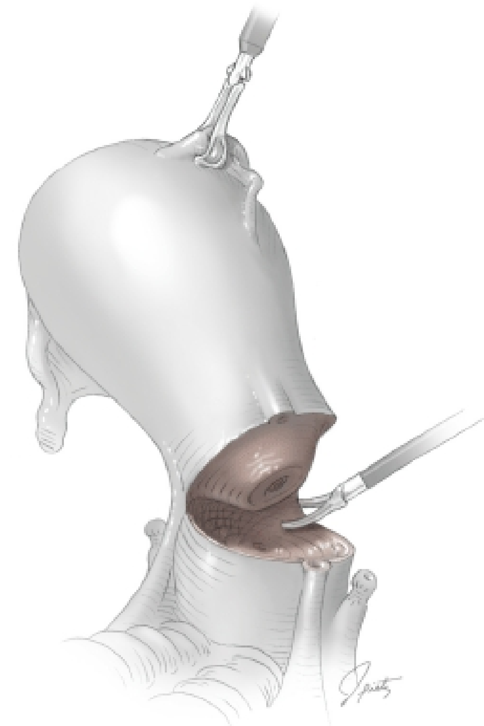
Once the corpus has been freed, it must be removed from the abdomen. Previously, colpotomy was used, but with the development of electric morcellating devices, vaginal removal of the specimen is no longer required. With most devices, tissue is grasped and drawn into a sheath that contains a rotating surgical blade to cut tissues. Because of the potential for surrounding organ injury, morcellators should not be moved toward the tissue of interest, but rather those tissues are brought to it (Milad, 2003).

Surgical Steps

1. **Initial Steps.** The initial surgical steps for LSH mirror those for LH, including coagulation of the uterine vessels (see Section 41-21, Laparoscopic Hysterectomy).

2. **Uterine Amputation.** The corpus is amputated from the cervix at a point just below the internal cervical os and superior to the uterosacral ligaments. A conical incision is extended down into the cervix to limit the possibility of residual endometrium (Fig. 41-22.1) (Jenkins, 2004). Additionally, at this point, adjunctive coring or ablation of the endocervical canal also may be performed to decrease the risk of long-term postoperative bleeding.

FIGURE 41-22.1



Source: Schorge JO, Schaffer JI, Halvorson LM, Hoffman BL, Bradshaw KD, Cunningham FG: *Williams Gynecology*: http://www.accessmedicine.com

Uterine amputation.

3. **Hemostasis.** Points of bleeding are cauterized, and the surgeon may elect to suture the peritoneum to cover the cervical stump. Alternatively, the use of absorbable adhesion barriers (Interceed, Johnson and Johnson, New Brunswick, NJ) at the surgical site is increasing in popularity.

4. **Laparoscopy Final Steps.** Completion of the procedure follows that for general laparoscopic procedures (see Laparoscopy).

Postoperative

Advantages to laparoscopy include a rapid return to normal diet and activities. Sexual intercourse, however, is delayed for several weeks following surgery to allow adequate healing.

41-23 TRACHELECTOMY

During the 1920s through 1950s, most abdominal hysterectomies were supracervical due to the lack of adequate blood banking and antibiotic therapy. For many women who had supracervical hysterectomy, later surgical removal of the cervix, which is termed *trachelectomy,* often was indicated for complaints of vault prolapse, persistent cyclic bleeding, or preinvasive cervical lesions (Pasley, 1988).

The cervix may be removed either vaginally or abdominally. However, for most women without concurrent pelvic pathology, vaginal trachelectomy is preferred (Pratt, 1976). With the resurgence of supracervical hysterectomy, now performed via laparoscopy, rates of trachelectomy for benign causes are expected to rise in the future.

Preoperative

PATIENT EVALUATION

As with hysterectomy, to exclude invasive cervical cancer, women preoperatively require Pap smear screening.

CONSENT

Trachelectomy is a safe and effective procedure. However, as with vaginal hysterectomy, patients are at risk for urinary tract and bowel injury. Similarly, postoperative vaginal cuff complications may include hematoma, abscess, and cellulitis. Fortunately, complications are infrequent for most. Although Pratt and Jeffries (1976) noted complications in 91 of 262 patients, complication rates in several series ranges below 10 percent (Welch, 1959; Riva, 1961).

PATIENT PREPARATION

Entry into the peritoneal cavity is common during trachelectomy. Accordingly, as with vaginal hysterectomy, antibiotic prophylaxis is warranted. Enemas the evening prior to surgery aid in evacuation of the rectum and minimize fecal soiling of the operative field.

Intraoperative

Surgical Steps

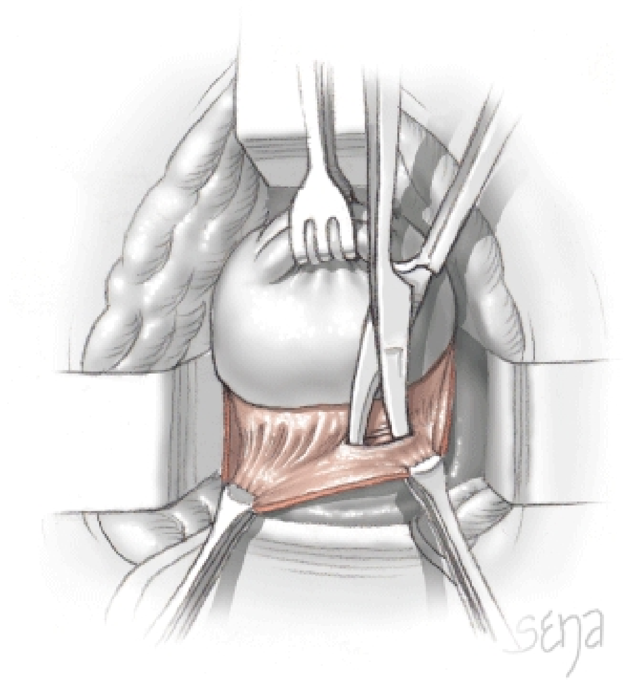
1. **Anesthesia and Patient Positioning.** For most women, trachelectomy is performed as an inpatient procedure under general or regional anesthesia. The patient is placed in a high or a standard dorsal lithotomy position, the vagina is surgically prepped, and a Foley catheter is placed.

2. **Vaginal Wall Incision.** The beginning steps of trachelectomy mirror those for vaginal hysterectomy (see Section 41-20, Vaginal Hysterectomy, steps 2 & 3).

3. **Extraperitoneal Dissection.** However, unlike vaginal hysterectomy, because the cervical stump lies outside the peritoneum, entry into the peritoneal cavity is not required for trachelectomy. Accordingly, following circumcision of the vaginal wall around the cervix, dissection proceeds to the vesicouterine fold but without peritoneal entry.

   In many cases, the bladder is more densely adhered to the anterior cervix. Thus, the clear tissue planes often encountered during vaginal hysterectomy are absent. Moreover, if at completion of the original hysterectomy the peritoneum was re-approximated to cover the cervical stump, then the bladder may be draped over and scarred to the apex of the stump as well. For this reason, dissection of the vaginal wall, bladder, and rectum from the surface of the cervix typically requires sharp rather than blunt dissection (Fig. 41-23.1). As with vaginal hysterectomy, outward traction on the cervix in combination with countertraction of the vaginal wall aids dissection. To avoid cystotomy and proctotomy, scissor blades and dissecting pressure are directed against the cervix.

FIGURE 41-23.1

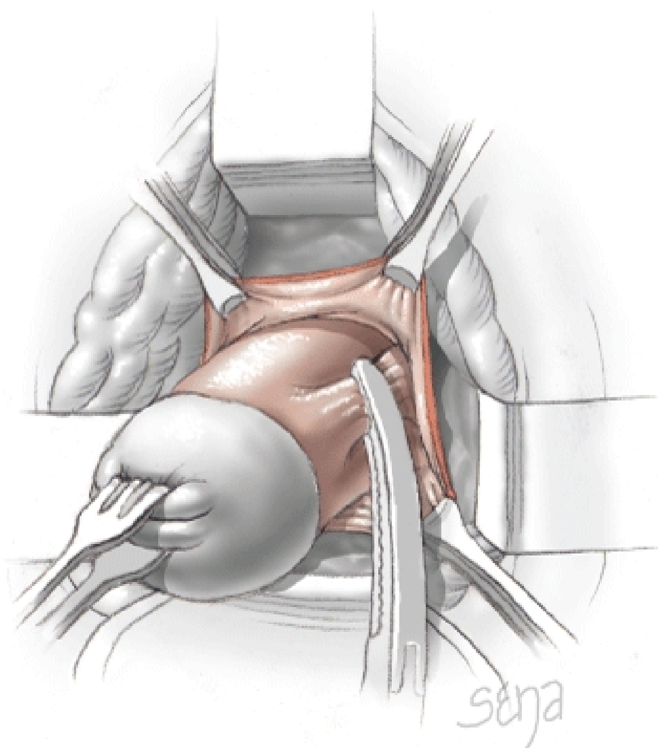


Source: Schorge JO, Schaffer JI, Halvorson LM, Hoffman BL, Bradshaw KD, Cunningham FG: *Williams Gynecology*: http://www.accessmedicine.com

Extraperitoneal dissection.

4. **Transection of Uterosacral and Cardinal Ligaments.** Once dissected free from the vaginal wall, the uterosacral and cardinal ligaments are clamped and ligated as with vaginal hysterectomy (Fig. 41-23.2). The cervical branches of the uterine artery typically are clamped and ligated within the cardinal ligament. Depending on cervical length, serial transection and ligation of the cardinal ligament are continued until the stump apex is reached.

FIGURE 41-23.2

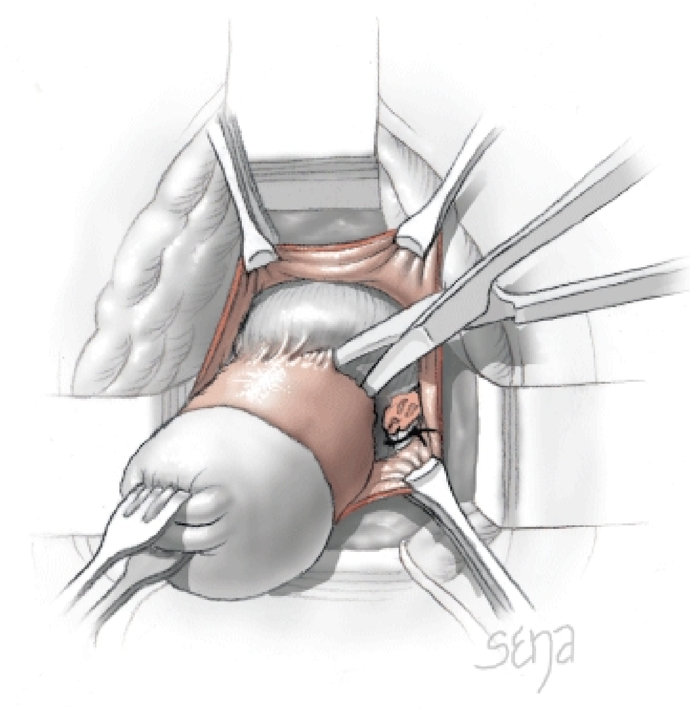


Source: Schorge JO, Schaffer JI, Halvorson LM, Hoffman BL, Bradshaw KD, Cunningham FG: *Williams Gynecology*: http://www.accessmedicine.com

Cardinal ligament.

5. **Stump Excision.** Once the apex is reached, sharp dissection across the top of the stump will free it from the vagina (Fig. 41-23.3).

FIGURE 41-23.3



Source: Schorge JO, Schaffer JI, Halvorson LM, Hoffman BL, Bradshaw KD, Cunningham FG: *Williams Gynecology*: http://www.accessmedicine.com

Stump dissection from peritoneum.

6. **Incision Closure.** Incorporation of the uterosacral and cardinal ligaments and re-approximation of the vaginal walls follow those for vaginal hysterectomy (Figs. 41-20.9 and 41-20.10).

Postoperative

As with hysterectomy, a significant number of women will have unexplained fever following trachelectomy. Pasley (1988), in his series of 55 patients, noted a rate of 9 percent. Similar to hysterectomy, patients with persistent or high-degree fevers require evaluation and antibiotic treatment.

41-24 INTERVAL PARTIAL SALPINGECTOMY

Interval partial salpingectomy is similar to puerperal midsegment salpingectomy and differs mainly in procedure timing and the method of abdominal entry. In contrast to postpartum or postabortal sterilization, the term *interval* designates performance unrelated in time to pregnancy. Accordingly, for most women undergoing interval sterilization, the uterus is small and lies within the confines of the pelvis. Thus, fallopian tubes are reached either laparoscopically or through a low transverse incision.

In general, with interval partial salpingectomy, a midtubal segment of fallopian tube is excised, and the severed ends seal by fibrosis and reperitonealization. Commonly used methods of interval sterilization include the Parkland, Pomeroy, and modified Pomeroy techniques (American College of Obstetricians and Gynecologists, 2003). Rarely, Irving and Uchida techniques are used.

With these latter two methods, increased dissection, operative time, and chance of mesosalpingeal injury are significant disadvantages.

Of methods for tubal sterilization, interval partial salpingectomy via laparotomy is selected infrequently, and only about 4 percent of women in the United States who elect sterilization undergo this procedure (Peterson, 1996). More commonly, laparoscopic techniques are employed mainly because of the postoperative advantages linked with laparoscopy (see Laparoscopy). Accordingly, interval partial salpingectomy typically is selected for cases in which laparoscopy may not be indicated, such as women with extensive adhesions, those with other concurrent pelvic pathology that dictates laparotomy, or situations in which laparoscopic equipment or surgical skills are lacking.

Preoperative

CONSENT

Prior to surgery, women can be reassured that partial salpingectomy is an effective method of sterilization. Pregnancy rates well less than 1 percent are typical. This result from tubal recanalization or technical errors, such as ligation of the wrong structure.

Tubal sterilization is a safe surgical procedure, and complication rates range below 2 percent (Pati, 2000). Of these, anesthesia complications, organ injury, and infection are the most frequent. In addition, although pregnancy is uncommon following sterilization, when pregnancy does occur, the risk of ectopic pregnancy is high and approximates 30 percent (Peterson, 1996; Ryder, 1999). However, because tubal sterilization is highly effective contraception, the overall risk of pregnancy is low, and therefore, so also is the risk of ectopic pregnancy.

Aside from physical risks, a small percentage of women experience regret following sterilization (see Chap. 5, Cautions). In studies, rates of regret approach 15 percent (Hillis, 1999; Trussell, 2003). For this reason, prior to surgery, women should be counseled about the risk of regret, the permanence of the procedure, and alternative effective long-term contraceptive methods.

Intraoperative

Surgical Steps

1. **Anesthesia and Patient Positioning.** Interval partial salpingectomy typically is an outpatient procedure performed under general anesthesia or regional analgesia. Following administration of anesthesia, the patient is placed supine, the abdomen surgically prepped, and the bladder is drained.

2. **Minilaparotomy.** For most patients, a 3- to 5-cm minilaparotomy incision cut at the level of the uterine fundus is sufficient and should follow the steps outlined in Section 41-2, Pfannenstiel Incision. Small Richardson or Army-Navy retractors provide adequate visualization in most cases. A uterine manipulator may be helpful in bringing the fallopian tubes into view.

3. **Tubal Identification.** A common reason for sterilization failure is ligation of the wrong structure, typically the round ligament. Identification and isolation of the fallopian tube prior to ligation and submission of tubal segments for pathologic confirmation therefore are required. In some women, especially those with associated tubal adhesions, this step may be challenging.

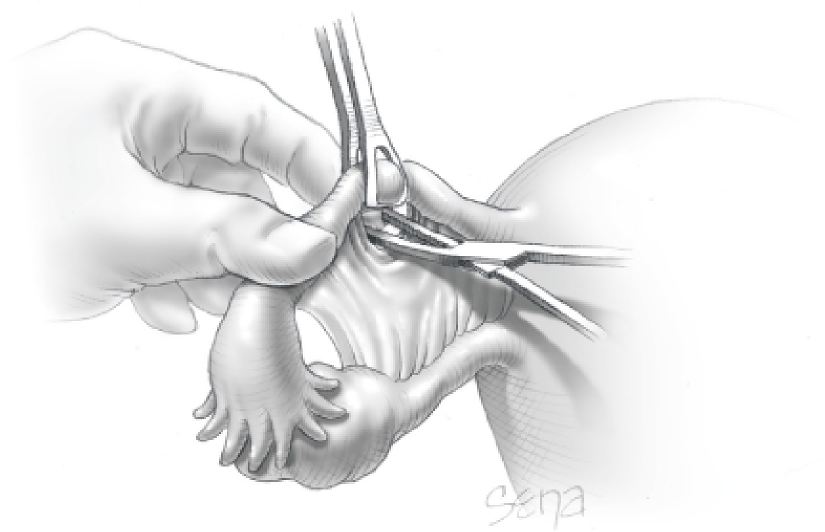
   Initially, the uterine fundus is identified. At the cornua, insertion of the fallopian tube lies posterior to that of the round ligament, and this orientation can guide a surgeon initially to the correct structure. A primary Babcock clamp is used to elevate the fallopian tube proximally, whereas a second grasps the tube more distally. The first clamp then is moved again and is placed distal to the second. The second then is removed and again placed distal to the first. In this manner, the surgeon "marches" down the length of the tube to reach the ampulla and identify the fimbria.

4. **Tubal Ligation.** At the midpoint of the tube, an avascular space in the mesosalpinx is identified, and a hemostat is placed directly beneath the tube. The hemostat is advanced bluntly through the mesosalpinx as counterpressure is applied with the index finger. The selected site should allow excision of a 2-cm segment that does not incorporate the fimbrial portion of the tube. Ligation of this portion leads to a greater risk of tubal recanalization and higher failure rates.

   The hemostat is advanced through the defect and gently opened to expand the aperture (Fig. 41-24.1). The end of a 2-0

chromic free tie is placed in the tip of the hemostat and pulled through the opening. This is repeated, bringing another tie through the rent. The distal portion of the midsegment is lifted, and the distal suture is tied. This elevation allows for a larger tubal segment to be obtained and helps the cut ends to remain widely separated. The second tie then is secured around the proximal fallopian tube.

FIGURE 41-24.1



Source: Schorge JO, Schaffer JI, Halvorson LM, Hoffman BL, Bradshaw KD, Cunningham FG: *Williams Gynecology*: http://www.accessmedicine.com

Parkland method: opening created in mesosalpinx.

5. **Tubal Excision.** The tip of Metzenbaum scissors is inserted through the mesosalpingeal defect, and the proximal portion of the tube is cut. A 0.5-cm pedicle is left to ensure that the tube will not slip through its ligature (Fig. 41-24.2). The inferior aspect of the tube is dissected sharply from the mesosalpinx toward the distal ligature, freeing the tube from the mesosalpinx. The distal end is excised above the suture, and an adequate 2-cm segment of tube is obtained. The pedicles and mesosalpinx are inspected for hemostasis. The procedure then is repeated on the other side.

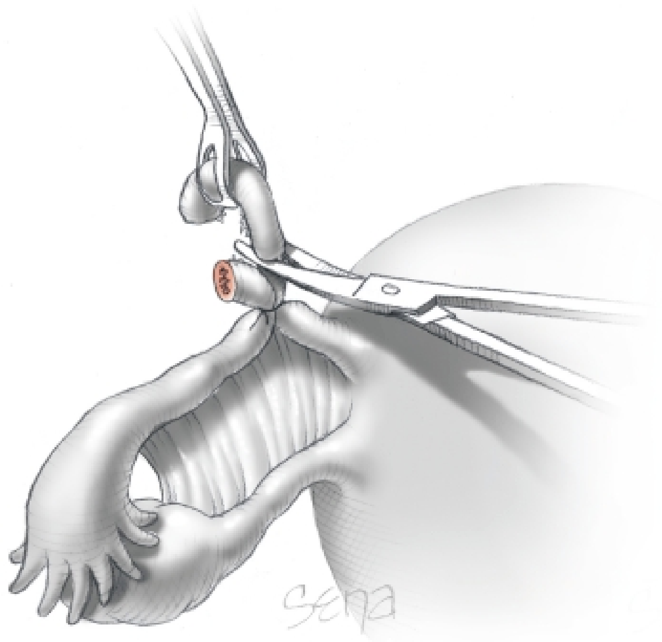
FIGURE 41-24.2

Source: Schorge JO, Schaffer JI, Halvorson LM, Hoffman BL, Bradshaw KD, Cunningham FG: *Williams Gynecology*: http://www.accessmedicine.com

Parkland method: tubal excision.

6. **Pomeroy Method.** This technique involves grasping and elevating a 2-cm midsegment of tube, ligating the tubal loop with a 2-0 chromic or plain catgut suture, and then excising the distal portion of the loop (Fig. 41-24.3). Prompt absorption of the suture following surgery causes the ligated ends to fall away, with a resulting 2- to 3-cm gap.

FIGURE 41-24.3

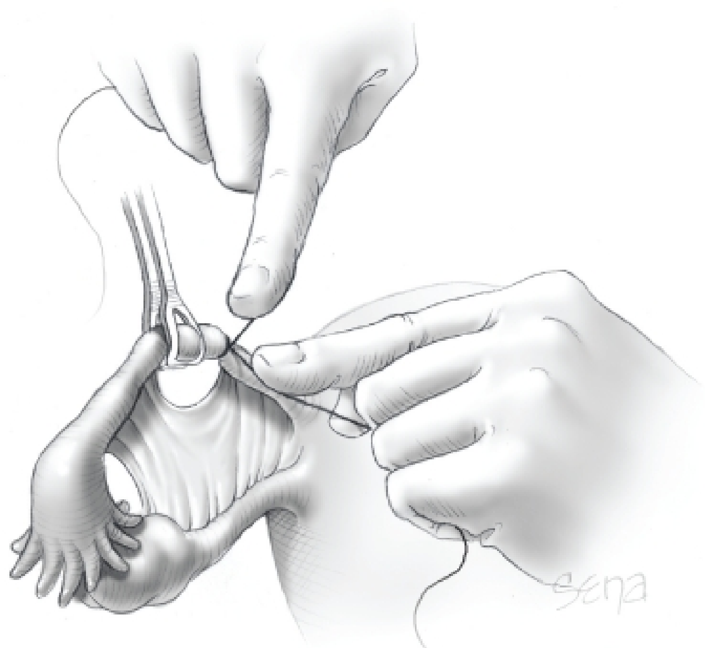


Source: Schorge JO, Schaffer JI, Halvorson LM, Hoffman BL, Bradshaw KD, Cunningham FG: *Williams Gynecology*: http://www.accessmedicine.com

Pomeroy method.

7. **Modified Pomeroy Method.** Many modifications of the Pomeroy technique have been described. One technique creates an avascular window in the mesosalpinx at a midpoint along the tube. Through this window, suture similar to that used for the Pomeroy method is passed. The portion of tube that lies proximal to this window is ligated first (Fig. 41-24.4). The long ends of this suture then are tied around the entire tubal loop, as in the Pomeroy method (Fig. 41-24.3). The distal portion of the loop is excised.

FIGURE 41-24.4

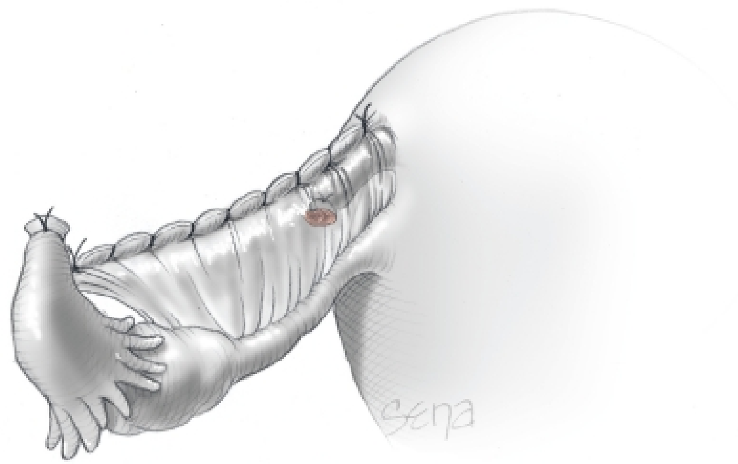


Source: Schorge JO, Schaffer JI, Halvorson LM, Hoffman BL, Bradshaw KD, Cunningham FG: *Williams Gynecology*: http://www.accessmedicine.com

Modified Pomeroy method.

8. **Uchida Method.** Tubal serosa is first separated from the muscularis by a subserosal injection of a dilute saline solution of epinephrine (1:100,000). A longitudinal incision is made in the ballooned serosa on its surface opposite the mesosalpinx. The serosal peritoneum then is grasped and dissected away from the underlying tubal muscularis. Following this dissection, a 5-cm midsegment of dissected fallopian tube is ligated proximally and distally with 2-0 chromic or plain catgut suture, and then resected. The raw serosal edges are reapproximated, burying the proximal cut tubal end within the leaves of the broad ligament and exteriorizing the distal end from the broad ligament (Fig. 41-24.5) (Sklar, 2004).

FIGURE 41-24.5

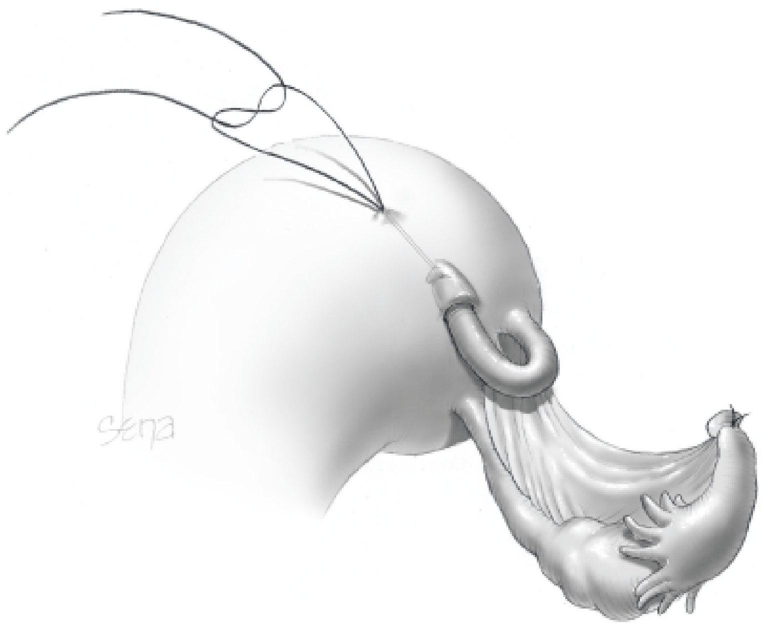


Source: Schorge JO, Schaffer JI, Halvorson LM, Hoffman BL, Bradshaw KD, Cunningham FG: *Williams Gynecology*: http://www.accessmedicine.com

Uchida method.

9. **Irving Method.** The Irving method begins similarly to the Parkland method. However, after the knot on the proximal tubal segment is secured, the ties are left long. Near the cornua, a 1-cm incision is made into the uterine serosa on the posterior uterine wall (Fig. 41-24.6). From this incision, a hemostat is used to tunnel into the myometrium, creating a 1- to 2-cm pocket that lies deep but parallel to the serosa. The two free ends of the proximal stump ligature then are threaded onto a curved needle. The needle is driven deep into the myometrial tunnel and exits out onto the uterine serosa. The needle is removed, and traction on the sutures pulls the proximal tubal stump into the pocket. Sutures then are tied on the outside of the serosa. The opening of the tunnel then is closed around the tube with interrupted 2-0 absorbable sutures.

FIGURE 41-24.6



Source: Schorge JO, Schaffer JI, Halvorson LM, Hoffman BL, Bradshaw KD, Cunningham FG: *Williams Gynecology*: http://www.accessmedicine.com

Irving method.

10. **Wound Closure.** The wound is closed as for other transverse abdominal incisions (see Section 41-2, Pfannenstiel Incision).

Postoperative

The recovery following minilaparotomy typically is rapid and without complication, and women may resume their regular diet and activities as tolerated. Sterilization is immediate following surgery, and intercourse may resume at the patient's discretion. Aside from regret, the risk of long-term physical or psychologicol sequelae is low. Peterson and co-workers (2000) found that women who had undergone tubal sterilization were no more likely than those without this surgery to have menstrual abnormalities. Moreover, interval tubal ligation is unlikely to result in changed sexual interest or pleasure (Costello, 2002).

41-25 SALPINGECTOMY AND SALPINGOSTOMY

Salpingectomy involves removal of the fallopian tube with sparing of the ovary. Its predominant use is in the treatment of ectopic pregnancy. This surgery, however, also may be employed to remove hydrosalpinges to improve in vitro fertilization (IVF) success rates or may be used as a method of sterilization (see Chap. 9, Hydrosalpinx). Alternatively, *salpingostomy* describes a lengthwise linear incision of the fallopian tube and typically is used to remove ectopic pregnancy contents (see Chap. 7, Salpingostomy).

Laparoscopic surgery offers patients the advantages of shorter hospitalizations, quicker recoveries, and less postoperative pain (Murphy, 1992; Vermesh, 1989). For these reasons, laparoscopic treatment of ectopic pregnancy generally is preferred.

As a result, laparotomic approaches for salpingectomy and salpingostomy are now reserved only for patients with ruptured ectopic pregnancies who are hemodynamically unstable or in those who have contraindications to laparoscopy. In these instances, laparotomy offers faster entry into the abdomen for control of bleeding and greater patient safety.

Preoperative

CONSENT

Most complications associated with salpingectomy and salpingostomy occur in conjunction with ectopic pregnancies, and the risk of bleeding is prominent. Injury to the ipsilateral ovary, however, is an attendant risk regardless of the indication. In certain cases, if severe, this damage can demand concurrent oophorectomy.

Persistent Trophoblastic Tissue

Following any surgical treatment of ectopic pregnancy, trophoblastic tissue can persist. Remnant implants typically involve the fallopian tube, but extratubal trophoblastic implants have been found on the omentum and on pelvic and abdominal peritoneal surfaces. Peritoneal implants typically measure 0.3 to 2.0 cm and appear as red-black nodules (Doss, 1998).

The risk of persistent trophoblast tissue is lower with salpingectomy than with salpingostomy. In addition, the risk is lowest with laparotomic salpingectomy because morcellation of the tube during laparoscopic salpingectomy also can leave trophoblastic tissue behind (Farquhar, 2005).

Preservation of Fertility

Most, but not all, studies show comparable subsequent fertility rates whether salpingectomy or salpingostomy is performed (Bangsgaard, 2003; Clausen, 1996; Mol, 1998; Tulandi, 1999). A further discussion of fertility and the long-term outcomes from these procedures can be found in Chapter 7, Salpingostomy. In the presence of a healthy contralateral tube, therefore, neither salpingostomy nor salpingectomy offers an advantage with respect to future fertility. However, salpingostomy should be considered as the primary treatment option for tubal pregnancy in the presence of disease in the contralateral tube and a desire for future fertility.

Unfortunately, in some cases of rupture, the extent of tubal damage or bleeding may limit tubal salvage, and salpingectomy may be required.

PATIENT PREPARATION

Salpingectomy and salpingostomy are associated with low rates of infection. Accordingly, preoperative antibiotics usually are not required.

Intraoperative

Surgical Steps

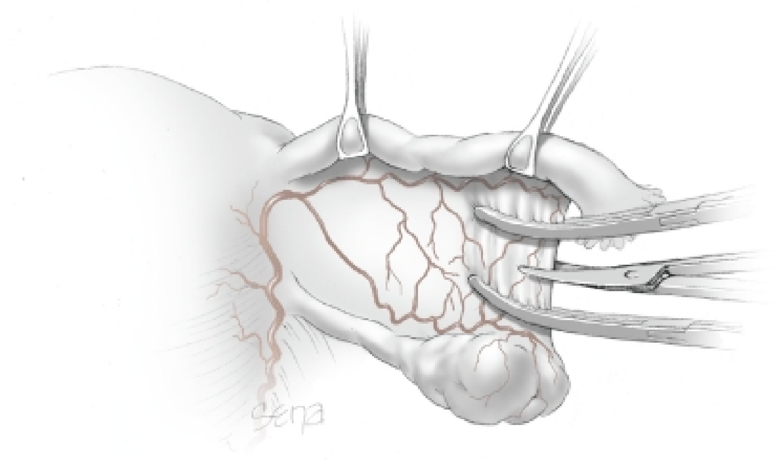
1. **Anesthesia and Patient Positioning.** In most cases of ectopic pregnancy managed by laparotomy, surgery is an inpatient procedure and requires general anesthesia. The patient is positioned supine, a Foley catheter is placed, and bladder is drained.

2. **Abdominal Entry.** The overwhelming majority of laparotomic salpingectomy procedures can be managed using a Pfannenstiel incision (see Section 41-2, Pfannenstiel Incision).

3. **Salpingectomy.** Once access to the pelvic organs has been reached, the adnexa are elevated and evaluated. For the affected fallopian tube, a Babock clamp is placed around the tube and directs the tube away from the uterus and ovary. This extends the mesosalpinx (Fig. 41-25.1).

   Beginning at the distal, fimbriated end of the tube, one Kelly clamp is placed across a 2-cm-long segment of the mesosalpinx, close to the fallopian tube. Another clamp is placed similarly but lies closer to the ovary. These clamps occlude vessels that traverse the mesosalpinx. Scissors then cut the interposed mesosalpinx.

FIGURE 41-25.1



Source: Schorge JO, Schaffer JI, Halvorson LM, Hoffman BL, Bradshaw KD, Cunningham FG: *Williams Gynecology*: http://www.accessmedicine.com

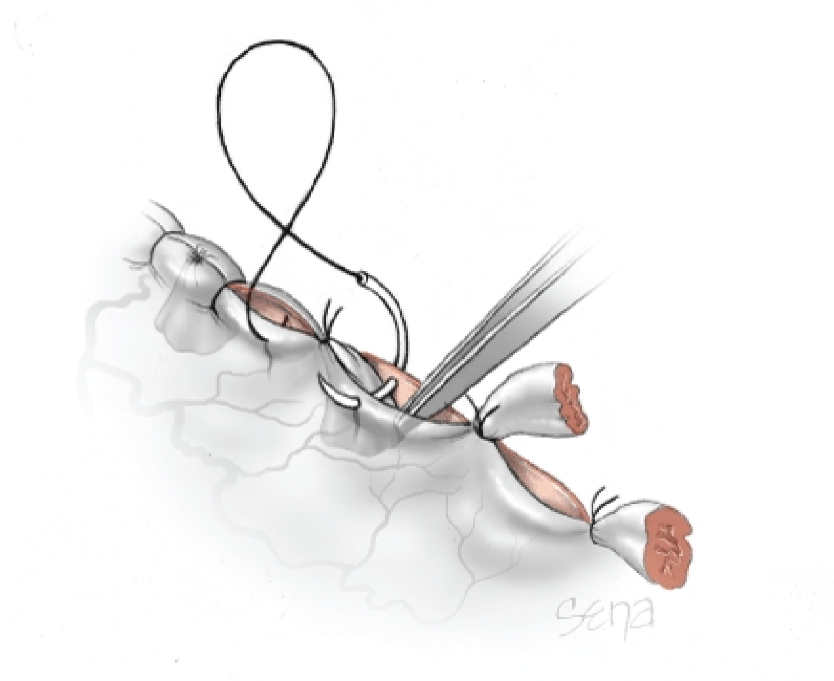
Salpingectomy.

4. **Vessel Ligation.** Each vascular tissue pedicle close to the ovary is tied with 2-0 or 3-0 delayed-absorbable suture. The clamp close to the tube may remain and is eventually removed with the tube. This step is repeated serially and with each clamping, an approximately 2-cm length of mesosalpinx is incorporated. Progression is directed from the ampullary end of the tube toward the uterus.

   The last clamp is placed across the proximal mesosalpinx and fallopian tube. Scissors then cut the mesosalpinx and free the tube from the uterus. This pedicle is similarly ligated with suture.

5. **Wound Closure.** If the surgeon so desires, the exposed vascular pedicles may be covered by a running suture that approximates the mesosalpinx (Fig. 41-25.2). The pelvis is irrigated and rid of blood and tissue dÃ©bris. The abdominal incision is closed as described in Section 41-2, Pfannenstiel Incision.

FIGURE 41-25.2



Source: Schorge JO, Schaffer JI, Halvorson LM, Hoffman BL, Bradshaw KD, Cunningham FG: *Williams Gynecology*: http://www.accessmedicine.com

Mesosalpinx closure.

6. **Salpingostomy.** Surgical steps for salpingostomy mirror those used in laparoscopic salpingostomy and can be reviewed in Section 41-31, Laparoscopic Salpingostomy.

Postoperative

In cases performed for ectopic pregnancy, salpingectomy or salpingostomy represents pregnancy termination. For this reason, the Rh status of the patient should be evaluated. Administration of 50 or 300 μg (1,500 IU) Rh_0 [D] immune globulin intramuscularly within 72 hours of pregnancy termination in Rh-negative women can lower the risk of isoimmunization in future pregnancies dramatically.

Because of the increased risk of persistent trophoblastic tissue in patients undergoing salpingostomy, serial weekly serum β-hCG levels should be measured until undetectable levels are reached. During this time, contraception should be used to avoid confusion between persistent trophoblastic tissue and a new pregnancy.

Resumption of activity and diet may follow that of a Pfannenstiel incision, as discussed in Section 41-2, Pfannenstiel Incision.

41-26 OVARIAN CYSTECTOMY

The removal of ovarian cysts usually is prompted by patient symptoms or by concerns of ovarian malignancy. Rather than excision of the entire ovary, removal of the cyst alone can offer women with ovarian pathology an opportunity to preserve hormone function and reproductive capacity (Maneschi, 1993). For these reasons, goals of ovarian cystectomy include gentle handling of tissues to limit postoperative adhesion formation and reconstruction of normal ovarian anatomy to aid the transfer of ova to the fallopian tube.

In some patients, a cystectomy may be performed laparoscopically rather than through laparotomy (see Section 41-33, Laparoscopic Ovarian Cystectomy). Several studies support the safe and effective use of laparoscopy for this problem (Lin, 1995; Mais, 1995; Pittaway, 1994; Yuen, 1997). Although laparoscopy is the preferred method of treatment, there are certain settings in which its role should be limited. In general, when a cyst is large, adhesive disease limits access and mobility, or the risk of malignancy is great, laparotomy instead should be performed. As summarized in Chapter 9, Surgical Excision, malignancy is suspected when cysts exceed 10 cm in diameter, concurrent ascites is present, preoperative serum tumor markers are elevated, and cyst contents appear complex or borders irregular on imaging.

Preoperative

CONSENT

In addition to the general surgical risks of laparotomy, the major risk of cystectomy is extensive bleeding from or injury to the ovary. These may necessitate removal of the entire ovary. If ovarian cancer is suspected prior to surgery, patients should be educated about the possibility surgical staging, including the need for hysterectomy and removal of both ovaries (see Chap. 35, Surgical Staging).

PATIENT PREPARATION

Antibiotics typically are not required preoperatively. If hysterectomy is required during ovarian staging, antibiotics may be given intraoperatively.

Intraoperative

Surgical Steps

1. **Anesthesia and Patient Positioning.** Because of the potential need for upper abdominal staging if malignancy is found, general anesthesia typically is indicated for this inpatient procedure. The patient is placed in a supine position, the abdomen and vagina are surgically prepped, and a Foley catheter is placed. Because of a possible need for hysterectomy if malignancy is found, the vagina should be included in the process.

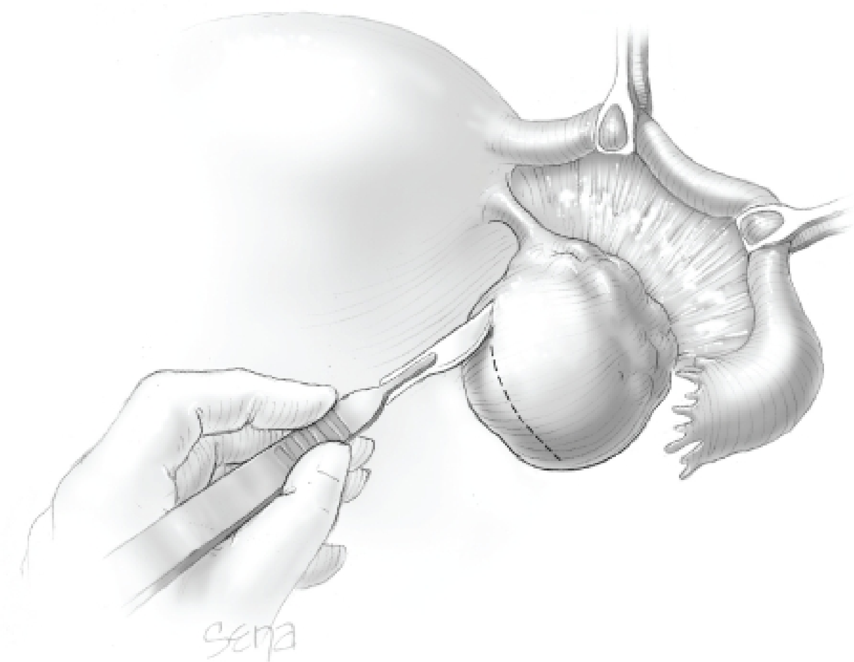
2. **Abdominal Entry.** Most ovarian cysts can be removed through a Pfannenstiel incision. Extremely large cysts or those in which a greater concern for malignancy is present may require a vertical incision. Vertical incisions allow adequate access to the upper abdomen if ovarian cancer staging is required.

   Cell washings from the pelvis and upper abdomen are collected. If a cancer is found, the washings are sent for cytologic analysis. If benign ovarian disease is found, then these washings may be discarded. The upper abdomen and pelvis are explored, and excrescences or suspicious areas are sampled and sent for frozen-section analysis.

   A self-retaining retractor is placed within the incision, and the bowel and omentum are packed from the operating field. The ovary is brought into view, and moist laparotomy sponges are placed in the cul-de-sac and beneath the ovary. This helps to minimize contamination of the pelvis if the cyst ruptures during excision.

3. **Ovarian Incision.** The ovary is held between the surgeon's thumb and opposing fingers. The ovarian capsule that overlies the dome of the cyst then is incised with either scalpel or electrosurgical blade. Care is taken to extend the incision deeply into the ovarian stroma to the level of the cyst wall but not to enter and rupture the cyst (Fig. 41-26.1). An intact cyst avoids spill of potentially malignant fluid into the peritoneal cavity. It also provides clearer planes of tissue dissection. Allis clamps are then placed on the incised edges of the ovarian capsule.

FIGURE 41-26.1

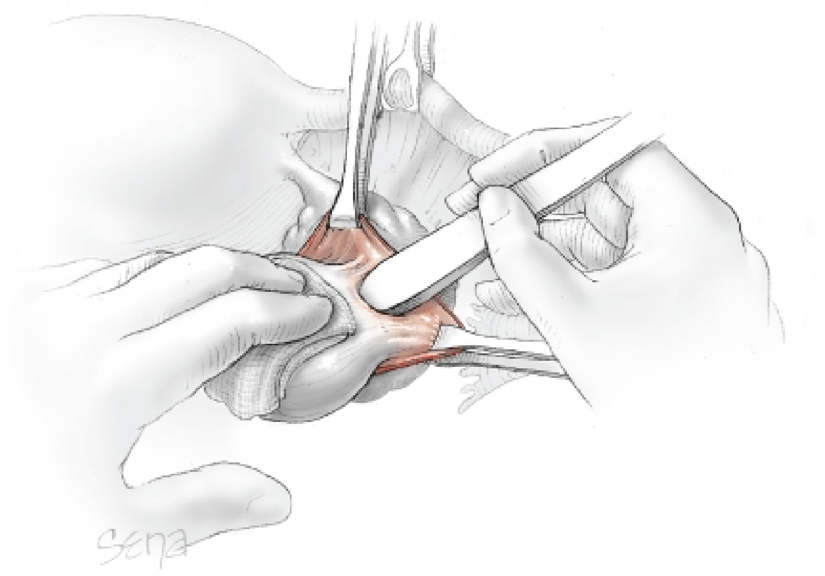


Source: Schorge JO, Schaffer JI, Halvorson LM, Hoffman BL, Bradshaw KD, Cunningham FG: *Williams Gynecology*: http://www.accessmedicine.com

Ovarian incision.

4. **Cyst Dissection.** Blunt dissection with fingertip or knife handle is used to develop a cleavage plane between the cyst wall and the remaining ovarian stroma (Fig. 41-26.2). In certain cases, adhesions may obliterate the cleavage plane, and sharp dissection with scissors may be necessary. As an assistant gently pulls the Allis clamps in a direction away from the cyst wall, the surgeon places fingers just above the advancing cleavage plane and pulls the cyst in the direction opposite the Allis clamps. Such traction and countertraction across the cleavage plane aids in dissection. Because the surface of the cyst wall may be smooth and slippery, the surgeon may place an unfolded thin gauze sponge between the fingers and the cyst wall to afford a better grip.

FIGURE 41-26.2



Source: Schorge JO, Schaffer JI, Halvorson LM, Hoffman BL, Bradshaw KD, Cunningham FG: *Williams Gynecology*: http://www.accessmedicine.com

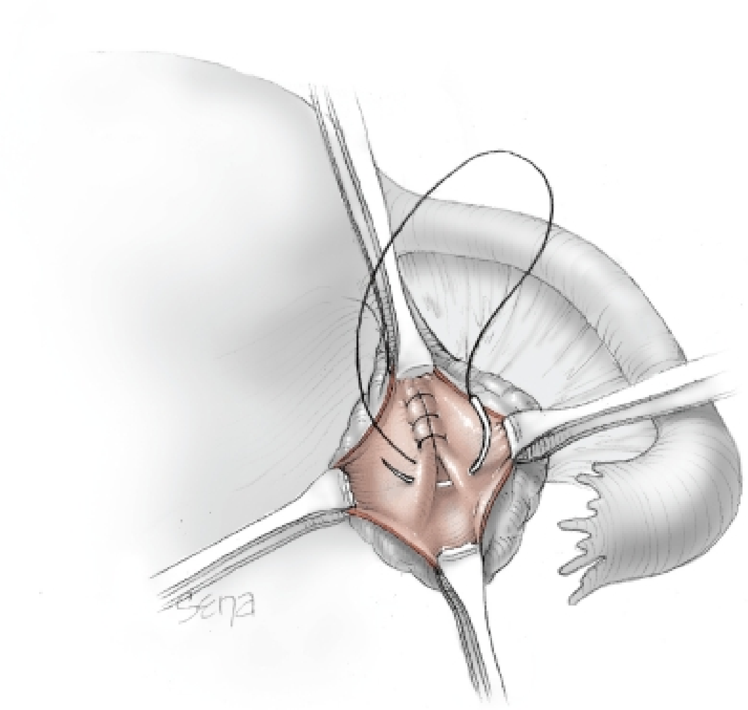
Cyst dissection.

5. **Cyst Excision.** Once the cyst is removed, it may be sent to the pathology department for frozen-section analysis. The ovarian bed is examined, and bleeding points are coagulated electrosurgically. In cases in which large cysts have stretched and thinned the ovarian surface, excess capsule can be removed sharply. This excision is performed to restore normal ovarian anatomy. Because ovarian follicles are contained within even extremely thinned capsules, however, care must be taken to preserve this tissue whenever possible.

6. **Ovarian Closure.** The ovarian bed then is closed in layers using 4-0 or 5-0 delayed-absorbable suture. These sutures re-approximate the ovarian tissue that previously surrounded the cyst on both sides (Fig. 41-26.3). In cases where the ovarian surface has been thinned, the needle tip should not be driven through the capsule. The resulting exposed suture on the ovarian surface may increase adhesion formation.

   The ovarian incision is closed with a running subcortical stitch (similar to subcuticular stitch) using 5-0 delayed-absorbable suture.

FIGURE 41-26.3



Source: Schorge JO, Schaffer JI, Halvorson LM, Hoffman BL, Bradshaw KD, Cunningham FG: *Williams Gynecology*: http://www.accessmedicine.com

Ovarian closure.

7. **Incision Closure.** Laparotomy sponges are removed from the cul-de-sac, and the pelvis is copiously irrigated with an isotonic solution such as lactated Ringer solution. The remaining packs and retractor are removed, and the abdominal incision is closed as described in Section 41-1, Midline Vertical Incision or Section 41-2, Pfannenstiel Incision.

Postoperative

After surgery, care may follow that described for laparotomy in general (see Section 41-1, Midline Vertical Incision).

41-27 OOPHORECTOMY

Removal of an ovary is performed more commonly by laparoscopy. However, laparotomy typically is indicated if the potential for malignancy is great, if the ovary is larger than 8 to 10 cm, or if significant adhesions are anticipated. In many of these instances, a salpingo-oophorectomy is performed, as presented in Section 41-19, Hysterectomy. However, if future fertility is desired, then the fallopian tube is preserved whenever possible.

Preoperative

PATIENT EVALUATION

Oophorectomy typically is performed to remove ovarian pathology that has been identified using transvaginal or transabdominal sonography. In patients in whom anatomy may be unclear, magnetic resonance (MR) imaging may add additional information. As

described in Chapters 35, Imaging and 36, Diagnosis, tumor markers may be drawn prior to surgery if malignancy is suspected.

CONSENT

In general, serious complications with oophorectomy are low and similar to those with other intra-abdominal surgeries. These include organ injury, hemorrhage, wound infection, and anesthesia complications. In addition, the risk of injury to the adjacent fallopian tube or ureter is small but should be specifically discussed during the consenting process. Ovarian cysts are the most common indication for oophorectomy. In these cases, if a malignant cyst ruptures and spills its contents, patients should be aware of the possible negative effects on prognosis.

PATIENT PREPARATION

Unless an ovarian abscess is identified, antibiotic prophylaxis is administered according to the preference of the surgeon.

Intraoperative

Surgical Steps

1. **Anesthesia and Patient Positioning.** Oophorectomy performed via laparotomy typically requires general anesthesia to allow staging of the upper abdomen if malignancy is found. Following administration of anesthesia, the patient is positioned supine, a Foley catheter is placed, and the abdomen is surgically prepped.

2. **Abdominal Entry.** Either a transverse or a vertical incision may be used for oophorectomy (Sections 41-1, Midline Vertical Incision and 41-2, Pfannenstiel Incision). Clinical factors such as ovarian size and risk of malignancy influence this selection.

3. **Exposure.** Following entry into the abdomen, a self-retaining retractor such as an O'Connor-O'Sullivan or Balfour retractor is placed. The pelvis and abdomen are explored visually and manually, and the bowel is packed from the operating field. The affected adnexa is grasped and elevated from the pelvis. If extensive adhesions are present, normal anatomic relationships are restored.

4. **Ureter Location.** Because of the close proximity of the ureter to the infundibulopelvic ligament, the ureter is identified prior to clamps being placed.

5. **Meso-ovarium.** The ovary is lifted from the pelvis and inspected. If malignancy is suspected, pelvic washings are obtained and set aside until analysis of a frozen-section sample from the affected ovary is completed. Two Babcock clamps are place at points equidistant along the fallopian tube length and are extended and retracted away from the ovary by an assistant. The ovary is elevated and placed on gentle tension in the opposite direction from the tube (Fig. 41-27.1). This effectively fans out the meso-ovarium.

   The first Pean clamp is placed close to the ovarian wall and across the distal meso-ovarium. Depending on the size of the ovary, this tissue pedicle may be cut and ligated with 2-0 delayed-absorbable suture prior to placement of the next clamp. Alternatively, especially with large cysts, serial clamps may be placed across the meso-ovarium in a line toward the uterus (Fig. 41-27.2). Small bites are taken to avoid kinking of the fallopian tube. Once the most medial clamp is placed is placed across the ovarian ligament, curved Mayo scissors can be used to cut between the clamps. The freed ovary is removed from the operative site and sent to pathology for evaluation. If malignancy is suspected, a frozen section analysis is requested. All clamps on the meso-ovarium then are ligated (Fig. 41-27.2).

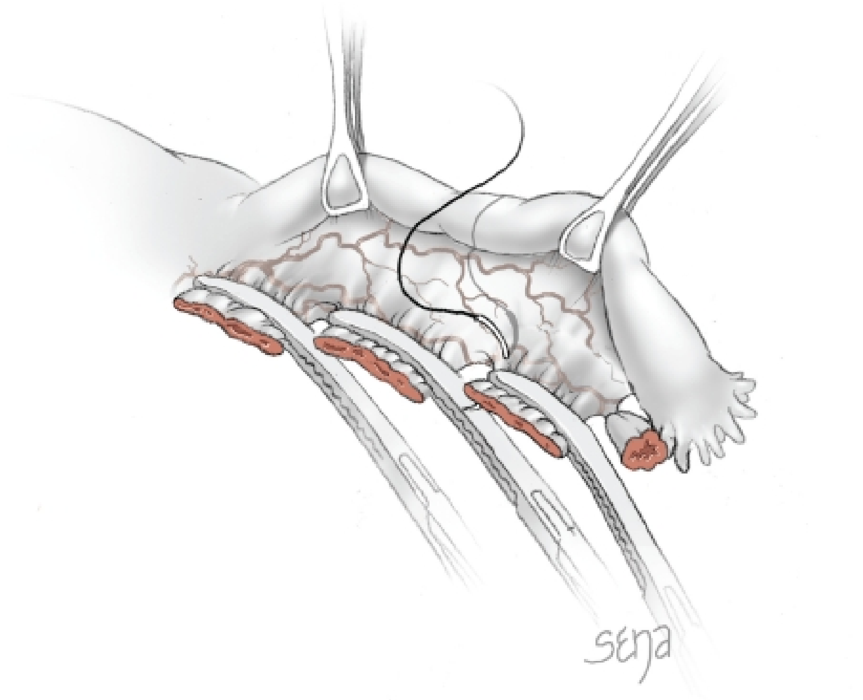
Clamping the meso-ovarium.

FIGURE 41-27.2



Pedicle ligation.

6. **Wound Closure.** The retractor and packing sponges are removed from the abdomen. The abdominal incision then is closed as described in Section 41-1, Midline Vertical Incision or 41-2, Pfannenstiel Incision.

Postoperative

Patient recovery typically is without complication and is similar to that described for hysterectomy (see Section 41-19, Hysterectomy). In reproductive-aged women, if only one ovary is removed, hormone and reproductive function is preserved. However, if both are excised, then surgical menopause follows, and hormone replacement may be considered, as described in Chapter 22, Current Approach to Hormone Replacement Administration.

41-28 LAPAROSCOPY

Operative laparoscopy provides minimally invasive options for women undergoing gynecologic surgery. Initially used in diagnostic and sterilization procedures, the spectrum of laparoscopic surgeries now includes hysterectomy, myomectomy, pelvic lymph node dissection, and others.

As a group, studies evaluating complications associated with this procedure have attested to its safety, and complication rates typically are below 4 percent (Bateman, 1996; Fuller, 2003; Harkki-Siren, 1997b; Mirhashemi, 1998). Logically, a greater risk of complication has been associated with complex operative procedures compared with diagnostic or sterilization procedures (Hulka, 1995). Specifically, laparoscopic hysterectomy (LH) appears to be associated with the highest rates (Harkki-Siren, 1997b).

Preoperative

CONSENT

Laparoscopy typically is associated with few complications. Of these, organ injury caused by puncture or by electrosurgery tools is the most common major complication. If this occurs, or if surgery is hindered by bleeding or adhesions, conversion to laparotomy may be necessary. Overall, this conversion risk is low and approximates 5 percent.

In addition to organ damage, nerve or vascular injury also may result. Because patients are placed during some procedures for extended periods in the dorsal lithotomy position with arms abducted, injury to the common peroneal, femoral, and ulnar nerves and to the brachial plexus is possible (Philosophe, 2003; Schwartz, 1993). Rarely, air embolism from gas insufflation following vessel puncture may occur.

Minor complications may include wound infection or hematoma, peritoneal irritation from retained intra-abdominal gas, subcutaneous emphysema, and vulvar edema. In contrast to these short-term problems, complications also may develop long after the surgery. Fortunately, incisional hernia formation following laparoscopy is infrequent, and trocar-site metastases develop uncommonly following cases in which malignancy is diagnosed.

In an attempt to identify risk factors for laparoscopic complications, Mirhashemi and co-workers (1998) found that increasing age and lower than average body mass index (BMI) were important factors. As noted earlier, complications also increase with the complexity of procedures performed.

Puncture Injuries

Because a sharp Verres needle and trocars may be used during laparoscopic entry, often blindly, risk for vessel and organ trauma is present. Risk factors have been identified, and these include intra-abdominal adhesions, insufficient gastric emptying, full bladder, insufficient pneumoperitoneum, poor muscle relaxation, thin patient habitus, and inappropriate angle or force of trocar insertion. As discussed below, several authors have advocated use of the open entry method as a means to lower rates of puncture injury (Catarci, 2001; Hasson, 2000; Munro, 2002).

Bowel Injury

The most common type of organ injury during laparoscopy is bowel injury and has been cited as 0.6 and 1.6 per 1,000 cases (Chapron, 1999; Harkki-Siren, 1997b). Women with previous laparotomy have a higher incidence of abdominal adhesions and are at greatest risk for this complication.

Unfortunately, bowel injury sustained during laparoscopy is often missed at the time of surgery. For example, in an observational study by Chandler and co-workers (2001), nearly 50 percent of both small and large bowel injuries were unrecognized for 24 hours or longer. Typically, these patients present with fever, abdominal pain, nausea, and vomiting within 48 hours of surgery (Li, 1997).

Preventative steps to avoid bowel injury in those with risks for abdominal adhesive disease include: (1) use of the open entry technique, (2) umbilical introduction of a microlaparoscope to scout for adhesions, and (3) primary trocar entry in the left hypochondrium rather than at the umbilicus. Palmer described a closed entry method that places the primary laparoscopic trocar at a point in the left midclavicular line 3-cm caudal to the costal margin (Fig. 41-28.1). In this region, visceral-parietal adhesions were found rarely (Ternamian, 2006). Lastly, decompression of the stomach with an orogastric tube prior to Verres needle placement can assist in lowering the risk of stomach puncture (Philosophe, 2003).

FIGURE 41-28.1

Abdominal access sites. **A.** Primary entry site in left upper quadrant entry at Palmer point. **B.** Primary entry site inferior to umbilicus. **C.** Accessory trocar sites.

Vascular Injury

Major vascular injury associated with laparoscopy is rare and typically results during primary trocar insertion. Rates of injury have been cited as 0.09 to 5 per 1,000 cases, and characteristically, the terminal aorta, vena cava, and iliac vessels have been injured (Bergqvist, 1987; Bonjer, 1997; Catarci, 2001; Nordestgaard, 1995).

Although infrequent, a significant number of deaths result from large vessel injury (Baadsgaard, 1989; Munro, 2002). Prevention may include use of the open entry technique or awareness of the angle and force of trocar entry. Despite these steps, though, if a large vessel is punctured, the Verres needle or trocar should not be removed because it may act as a vascular plug. Laparotomy, direct manual pressure on the vessel, and notification of a vascular surgeon should follow.

In contrast, if the inferior epigastric artery is injured, several simple techniques can control hemorrhage. First, electrosurgical coagulation of the bleeding site may suffice in many cases. If this is unsuccessful in controlling bleeding, a 14F Foley catheter can be threaded through the cannula of the wounding trocar or through the defect created by this trocar. The Foley balloon then is inflated and pulled upward to create pressure against the posterior surface of the anterior abdominal wall. At the skin surface, a Kelly clamp is placed perpendicular across the Foley catheter and parallel to the skin to hold the balloon firmly in place. The balloon and catheter can be removed 12 hours later. Alternatively, Chatzipapas and Magos (1997) described a process that directs sutures from the skin surface through the abdominal wall and peritoneum to arch under the bleeding vessel to allow direct vessel ligation (Fig 41-28.2).

FIGURE 41-28.2

A. Suture with an attached straight needle is driven through the anterior abdominal wall lateral and caudal to the bleeding vessel. This is performed using direct laparoscopic visualization to avoid organ injury. A laparoscopic needle driver or atraumatic grasping forceps grabs the needle. Both needle and driver are drawn up and out of a contralateral cannula. **B.** A similar procedure is repeated medial and caudal to the bleeding vessel. **C.** The needles are cut from the two suture strands and are tied together outside the abdominal cavity. The knot is dragged back through the cannula. This creates a suture sling caudal to the point of vessel bleeding. **D.** Both suture strings then are tied again outside the abdomen over a pressure dressing to occlude the caudal portion of the inferior epigastric vessel. The entire process is repeated cephalad to the bleeding vessel. (Modified from Chatzipapas, 1997, with permission.)

Urinary Tract Injury

Bladder puncture is an uncommon risk of laparoscopy, but with the increasing use of laparoscopic hysterectomy techniques, rates of ureteral injury have increased. Bladder decompression prior to and during surgery and careful placement of secondary trocars will prevent many cases of injury.

Thermal Injury

Electrosurgical complications may lead to accidental burns by direct contact of the instrument or by stray electric current. Fortunately, the risk of this complication is low. For example, Meikle and co-workers (1997) noted a thermal bowel injury rate of 4 per 1,000 laparoscopically assisted vaginal hysterectomy (LAVH) cases. In addition to the bowel, thermal injury also can lead to

ureteral stricture and urinary tract fistula formation.

Steps to avoid these injuries include keeping instrument tips within the visual field when electric current is applied, strict instrument maintenance to identify insulation defects, employment of bipolar coagulation for hemostasis when feasible, and use of lower-voltage (cutting) current whenever possible to reduce the applied voltage (Wu, 2000).

Incisional Hernia

Incisional hernias have been described as a potential long-term consequence of laparoscopy. The incidence approximates 1 percent but may rise in the future with the increasing use of larger trocars for operative laparoscopy. Approximately one fourth of hernias are umbilical, and the remainder develop at secondary trocar sites (Lajer, 1997).

A major risk for this complication is the use of large trocars measuring 10 mm or greater in diameter. Accordingly, to reduce the frequency of these hernias, it is recommended to use smaller trocars when possible and to use a fascial suture closure at larger trocars wound sites. Similarly, the use of conical tipped trocars as opposed to pyramidal trocars has shown to lower this incidence (Leibl, 1999). Finally, care should be taken to ensure that peritoneal tissue is not drawn into the trocar canals when removing the cannulas (Boughey, 2003; Montz, 1994).

Trocar-Site Metastasis

Rates of trocar-site cancer metastasis are low and complicate the clinical course of approximately 1 percent of patients in whom gynecologic malignancy is identified (Childers, 1994). Although most trocar-site metastases are associated with advanced stages of disease, metastasis has followed surgery for tumors of low malignant potential. As a result, the components of laparoscopy itself have been evaluated as a risk for tumor spread to the trocar sites (Ramirez, 2004). Currently, no evidence-based consensus addresses prevention of this complication.

PATIENT PREPARATION

Overall, laparoscopy has been associated with lower rates of postoperative infection than laparotomy. Therefore, the decision to administer antibiotics with laparoscopic procedures is influenced by the procedure itself and not the approach.

Intraoperative

INSTRUMENTS

Because of the small incisions employed with laparoscopy and the increased distance between surgeons and their operative field, specialized instruments have been developed (Fig. 41-28.3).

Uterine Manipulator

During laparoscopy, manipulation of the uterus allows improved visualization of cul-de sac structures and aids in creating countertraction on lateral pelvic structures during operative procedures. For this purpose, a uterine manipulator is placed into the endocervical canal or endometrial cavity. Several types of manipulators have been designed, but the uniting principle is a rigid,

hollow-bore device whose cephalad end is inserted into the endocervical canal or endometrial cavity and whose stiff caudal stem spans the vagina and exits the introitus to allow manipulation by the surgeon or assistant. Additionally, the device's hollow bore permits chromotubation (Figs. 41-28.4 and 41-28.5).

FIGURE 41-28.4

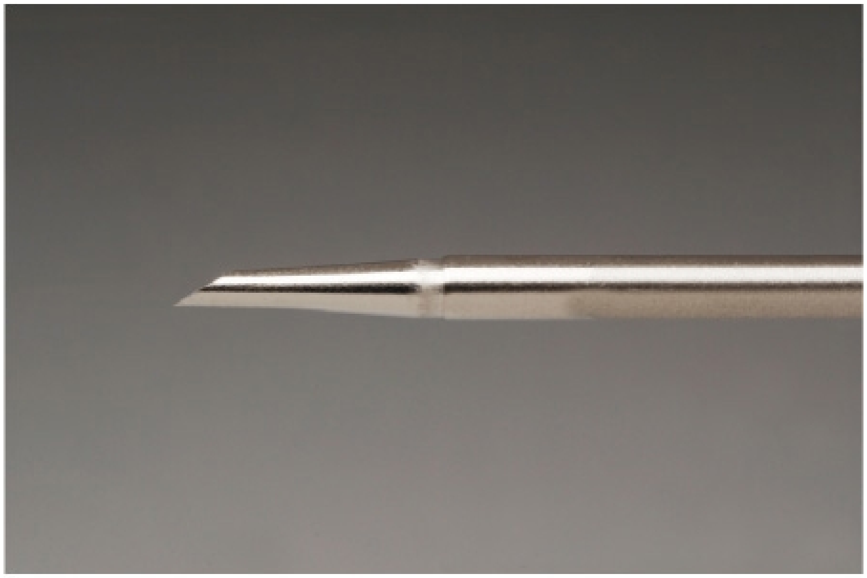
A balloon-type uterine manipulator. The deflated balloon tip is inserted into the endometrial cavity. The balloon is inflated to hold the stiff manipulator in place.

Verres Needle

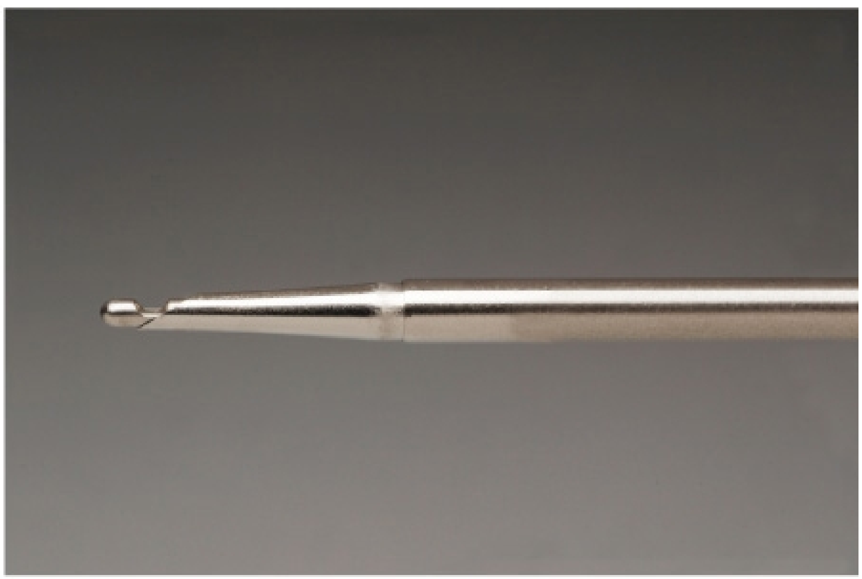
Several techniques can be used to initially enter the abdominal cavity. The most common method employed by gynecologists uses a long, slender needle, called a *Verres needle,* to conduct gas into the abdomen and create a pneumoperitoneum (Fig. 41-28.6). The pressure and peritoneal tenting created by this gas aid entry of the first trocar.

FIGURE 41-28.6



A

Source: Schorge JO, Schaffer JI, Halvorson LM, Hoffman BL, Bradshaw KD, Cunningham FG: *Williams Gynecology*: http://www.accessmedicine.com



B

Source: Schorge JO, Schaffer JI, Halvorson LM, Hoffman BL, Bradshaw KD, Cunningham FG: *Williams Gynecology*: http://www.accessmedicine.com

The Verres needle consists of a sharp outer needle **A.** which houses a blunt-tipped, spring-loaded inner stylet **B.** (Courtesy of Ethicon.)

With insertion of the Verres needle, tissue resistance compresses an inner spring, and a blunt stylet, which is slightly longer than the sharp external needle sheath, retracts. The stylet remains retracted until the sharp tip of the external needle sheath pierces the peritoneum. At this point, tissue resistance disappears, and the blunt stylet is pushed forward by the inner spring to prevent organ or vessel injury. This self-retracting concept is seen again in the design of disposable trocars with retractable shields.

Abdominal Trocars

Trocars are used gain access to the abdominal cavity. First-generation trocars consist of a hollow, long, slender cannula that sheaths an inner stylet. Trocars typically range from 5 to 12 mm in diameter, and their tips may be either conical, pyramidal, or blunt (Fig. 41-28.7).

FIGURE 41-28.7

Source: Schorge JO, Schaffer JI, Halvorson LM, Hoffman BL, Bradshaw KD, Cunningham FG: *Williams Gynecology*: http://www.accessmedicine.com

Trocars consist of outer cannula and inner obturator. The trocar is used to gain access to the abdomen. The obturator then is removed, and the cannula serves as a conduit through which to introduce instruments. Obturators may have a pyramidal (top), conical (middle), or blunt tip (bottom). (Courtesy of Karl storz America, Inc.)

Conical trocars are smooth except for their pointed tip and therefore have no cutting edges. They split the fascia rather than cut it and thus are preferred by some to lower the risk of vessel injury and postoperative hernia formation (Hurd, 1995; Leibl, 1999). They require more penetration force to insert, however. In contrast, pyramidal trocars have sharp edges and tip and as result, cut the fascia as they are inserted into the abdomen.

In the 1980s, trocars with retractable shields were introduced. Similar, to the concept used with the Verres needle, a hollow plastic retractable shield covers the trocar tip both before and after the trocar pierces the abdominal wall. In this manner, the cutting edge is exposed only during its passage through the fascia. Despite theoretical advantages to these shielded trocars in preventing organ injury, studies have failed to show their superiority (Fuller, 2003).

Suction-Irrigation Systems

During laparoscopic procedures, irrigation and suctioning of electrosurgical smoke, blood, or irrigation fluids is often required. For this reason, suction-irrigation systems have been developed to offer both modalities through a 5-mm hollow-bore rod (see Fig. 41-28.2A).

Specimen Bags

Certain surgeries such as ovarian cystectomy require removal of specimens in a manner that minimizes contamination of these specimens or their contents to the operating field. Accordingly, purse-string endoscopic bags have been developed (Endo Catch,

Auto Suture, Norwalk, CT; Endosac, Zenith Medical, SanDiego, CA) (Fig. 41-28.8).

Electrosurgery

Suture ligatures for hemostasis are more difficult to apply during laparoscopy. Accordingly, electrosurgical coagulation takes on added importance, and both unipolar and bipolar modalities can be used. A fuller discussion of electrosurgical principles can be found in Chapter 40, Electrosurgery.

Disposable versus Reusable

The instruments just described are available in both reusable and disposable forms, each having its own advantages. The main advantage to reusable instruments is lowered expense. Cost analyses have demonstrated that disposable instruments add significant cost compared with reusable ones (Campbell, 2003; Morrison, 2004).

The main advantage to disposable instruments stems from the consistent sharpness of laparoscopic Verres needles, trocars, and scissors and from avoidance of lost instrument parts. For example, Corson and associates (1989) showed that reusable trocars, although sharpened at regular intervals, still required twice the force for entry compared with disposable trocars. Dull scissors may lead to longer operating times and ineffectual surgical technique. As a result, these advantages and disadvantages must be balanced when selecting either a reusable or disposable instrument with laparoscopy.

Carbon Dioxide Insufflation

Carbon dioxide (CO_2) is currently the insufflation gas of choice for laparoscopy. It fulfills most of the requirements for an ideal insufflation gas, being colorless, noninflammable, and rapidly excreted from the circulation. However, disadvantages include CO_2 absorption across peritoneal surfaces into the circulation; constant gas leaks, which prolong surgery; and peritoneal irritation due to conversion of CO_2 to carbonic acid. Moveover, retained intra-abdominal gas can lead to diaphragmatic irritation and referred neck and shoulder pain postoperatively.

To counter these potential problems with CO_2 use, gasless laparoscopy has been described. This technique uses a device with fan bladeâ€"shaped retractors attached to the end of a rod. The blades of the device are placed along the peritoneal surface of the anterior abdominal wall, and the rod extends up through the umbilical incision. An electric lift attaches to the rod and elevates the anterior abdominal wall. As opposed to the dome shape created by a pneumoperitoneum, gasless devices create a truncated pyramidal shape.

Despite advantages, drawbacks with gasless laparoscopy currently limit its routine use, although it still may have value in high-risk patients with cardiorespiratory diseases (Cravello, 1999; Goldberg, 1997; Negrin Perez, 1999).

Surgical Steps

1. **Anesthesia and Patient Positioning.** Most laparoscopic surgery is performed in an operating room and requires general anesthesia. Some investigators, however, have described in-office microlaparoscopy using 2- to 3-mm microlaparoscopes for such diverse uses as second-look evaluation of cancer treatment, sterilization, and pelvic pain and infertility evaluation (Franchi, 2000; Kovacs, 1998; Mazdisnian, 2002; Palter, 1999).

   For the anesthesiologist, patient positioning and gases used for abdominal insufflation can create specific concerns. For example, Trendelenburg positioning of the patient enables bowel repositioning for the surgeon. But as a result of increased pressure against the diaphragm by abdominal contents, ventilation may be more difficult. Similarly, distention of the abdominal cavity with CO_2 gas under pressure also can add to ventilatory resistance. Another concern with the distending medium stems from its absorption into the bloodstream. Depending on the length of the operation, significant volumes of CO_2 can be absorbed and lead to hypercarbia. A final consideration is gastric decompression, and an orogastric tube is recommended by many. This preventative measure decreases the risk of stomach puncture by the Verres needle or trocar during their insertion (Chapron, 1999).

   Once adequate anesthesia has been delivered to allow manipulation of the uterus, the patient is placed in a dorsal lithotomy position. Correct patient positioning is critical to avoiding nerve injury, which and is discussed in Chapter 40, Patient Positioning. The vagina and abdomen should be surgically prepped and the bladder drained. If a longer procedure is anticipated, a Foley catheter may be required because a full bladder can obstruct the operating view and increase the risk of bladder injury.

2. **Uterine Manipulator Placement.** The surgeon is double gloved to allow placement of the uterine manipulator. Vaginal retractors are used to display the cervix, and a single-toothed tenaculum is placed on the anterior cervical lip. A Cohen uterine manipulator then is inserted into the external cervical os. Alternatively, the balloon end of an endometrial cavity manipulator may be threaded into the endometrial cavity. The outer pair of surgical gloves is removed, and the surgeon moves to one side of the patient.

3. **Primary Trocar Entry.** There are four basic techniques to place the trocar that will house the laparoscope: (1) Verres needle insertion, (2) direct trocar insertion, (3) optical access insertion, and (4) open entry methods. The first three are classified as *closed entry* techniques in contrast with the *open entry* method.

   Closed entry techniques offer quick access to the abdominal cavity with a low risk of complications (Bonjers, 1997; Catarci, 2001). These techniques are best performed with supine patients lying in a horizontal plane. Although most gynecologic laparoscopy is performed with patients in the Trendelenburg position, this position is dangerous for the initial entry portion of the procedure. In Trendelenburg position, the aortic bifurcation lies directly below the umbilicus and thus is more vulnerable to puncture.

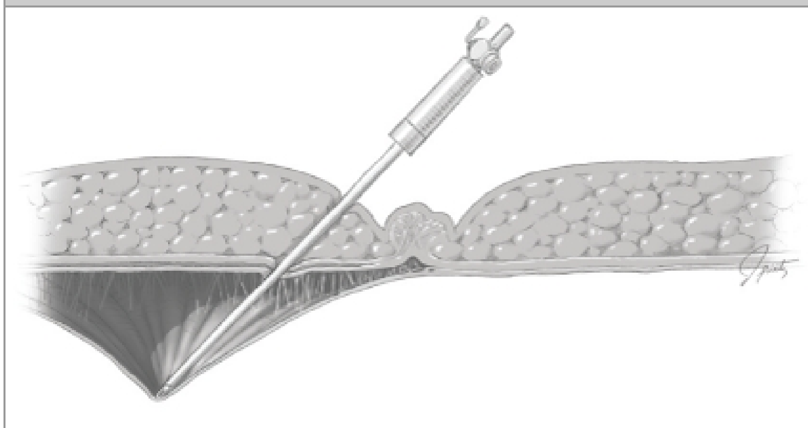
   In most cases, the umbilicus is chosen as the site of entry because it is relatively avascular and the thinnest accessible portion of the anterior abdominal wall (see Fig. 38-2). An incision that will accommodate the laparoscopic trocar should be made along Langer lines for best cosmetic results. These lines reflect the natural skin tension lines created by arrangement of underlying skin collagen.

4. **Verres Needle Entry.** Entry using a Verres needle is a two-step process. First, the Verres needle tip is placed intra-abdominally to allow partial insufflation of the abdomen. Then puncture of the fascia and the peritoneum follows with a larger trocar.

   Prior to needle placement, the anterior abdominal wall is elevated by grasping the wall caudal to the umbilicus with one hand. This distances the abdominal wall from the intra-abdominal contents by 6 to 8 cm. If the patient is overweight, two towel clamps can be used on each side of the umbilicus to achieve a similar effect.

   The Verres needle is inserted at a 45-degree angle from vertical and is directed along the midline toward the pelvis (Fig. 41-28.9).

FIGURE 41-28.9



Source: Schorge JO, Schaffer JI, Halvorson LM, Hoffman BL, Bradshaw KD, Cunningham FG: *Williams Gynecology*: http://www.accessmedicine.com

Verres needles tenting the peritoneal layer.

5. **Placement Confirmation.** Entry failure with this method usually stems from placement of the Verres needle tip in the preperitoneal space rather than within the abdominal cavity. Therefore, confirmation of intra-abdominal positioning prior to gas instillation is critical. For confirmation, 10 mL of saline can be injected through the needle following placement. Injection with an inability to re-aspirate the fluid is presumptive of correct placement. Similarly, if a drop of saline that has been placed on the external end of the Verres needle is sucked quickly into the abdominal cavity, then correct placement is likely.

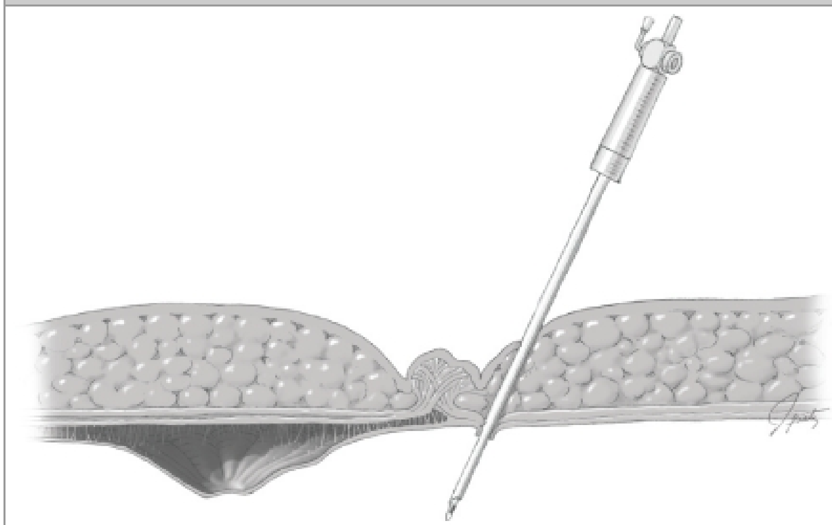
6. **Gas Insufflation.** Following needle puncture and placement verification, the abdomen is insufflated with CO_2 to reach an intra-abdominal pressure of 10 to 12 mm Hg. In many patients, this correlates with an infusion of 2.5 to 3 L of gas.

7. **Primary Trocar Insertion.** The Verres needle is removed, the abdominal wall below the umbilicus is manually elevated, and a trocar is placed in the umbilical incision. The insertional angle of this trocar mirrors that of the Verres needle. The trocar punctures the fascia and underlying peritoneum and enters the abdominal cavity. A gas rushing sound characteristically confirms placement.

8. **Abdomen Insufflation.** The abdomen then is further insufflated as needed. A constant intra-abdominal pressure of 10 to 15 mm Hg is optimal for laparoscopy. Higher pressures can result in ventilatory difficulties. With most equipment in use today, a surgeon can set a maximal abdominal pressure beyond which flow of gas ceases automatically.

9. **Incorrect Needle Placement.** Failures can occur with this method and stem from incorrect needle placement with creation of preperitoneal emphysema (see Fig. 41-28.9). This gaseous dissection of the peritoneum away from the anterior abdominal wall hinders the trocar in piercing the peritoneum. Instead, the trocar further stretches and pushes the peritoneum internally. This problem fortunately often can be overcome by a second attempt with the Verres needle above the umbilicus (Fig. 41-28.10).

FIGURE 41-28.10



Source: Schorge JO, Schaffer JI, Halvorson LM, Hoffman BL, Bradshaw KD, Cunningham FG: *Williams Gynecology*: http://www.accessmedicine.com

Verres needle replacement above the umbilicus.

10. **Direct Trocar Entry.** Because of entry failures associated with preperitoneal insufflation, a direct entry method was evaluated subsequently (Copeland, 1983; Dingfelder, 1978). The procedure involves lifting the abdominal wall and directly piercing and entering the anterior abdominal wall without prior insufflation.

    Several comparative studies between Verres needle and direct trocar techniques have shown lower rates of entry failure with the direct method (Byron, 1993; Clayman, 2005; Gunenc, 2005). Moreover, these investigators found comparable or lower associated minor complication rates with direct trocar entry.

11. **Optical Access Trocar Entry.** To lower the risk of bowel injury at the time of primary trocar insertion, optical trocars were developed in the early 1990s. These devices, in essence, combine the laparoscope and trocar into one tool. During use, the optical trocar transmits images of the abdominal wall layers to a television monitor. These layers then are cut under direct visualization by advancement of the sharp trocar edge.

    Despite the theoretical advantage to this type of trocar, major organ injury still has been reported with use of optical access trocars. Moreover, no large studies have been performed to establish its clinical superiority over other closed entry techniques (Sharp, 2002).

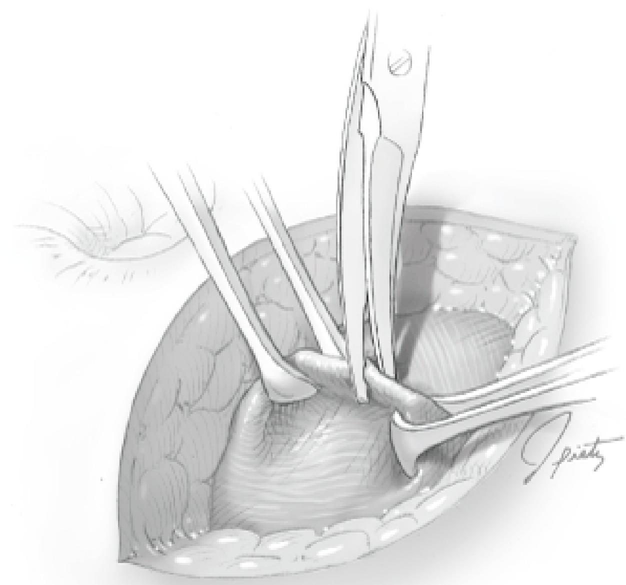
12. **Open Entry.** Because of associated risks of puncture injury with the closed entry techniques, an open entry technique was described by Hasson (1971, 1974). This technique requires use of a trocar composed of a blunt-tipped obturator that is sheathed by an outer cannula. It is recommended by many surgeons for patients with prior abdominal surgery, for those following a closed technique entry failure, and for pediatric patients (Madeb, 2004).

    In a retrospective review of more than 5,000 open entry procedures, Hasson and associates (2000) noted that minor and medium-risk complications developed at a rate of 0.5 percent. Moveover, in studies comparing open and closed techniques, open methods showed lower rates of entry failure and organ injury (Bonjers, 1997; Merlin, 2003). This technique, however, is not foolproof, and organ injury, mainly bowel, has been described (Magrina, 2002). Typically, this method of entry takes longer than closed entry, and the pneumoperitoneum can be difficult to maintain in some cases due to air escape from around the cannula.

13. **Umbilical Incision for Open Entry.** A 1- to 2-cm transverse incision at the lower edge of the umbilicus is made while applying tension with fine-toothed forceps to its lateral borders. Skin edges are retracted laterally to expose the linea alba, and the fascia is dissected free of adhesions and adipose tissue.

    The fascia is lifted and everted upward with two Allis clamps (Fig. 41-28.11). A 0.5- to 1-cm incision with scalpel or scissors then transects the fascia. The Allis clamps are repositioned, one on each free fascial edge.

FIGURE 41-28.11

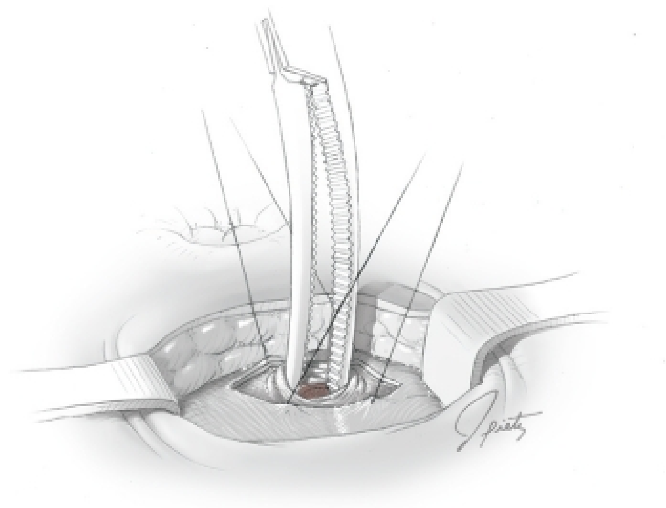


Source: Schorge JO, Schaffer JI, Halvorson LM, Hoffman BL, Bradshaw KD, Cunningham FG: *Williams Gynecology*: http://www.accessmedicine.com

Fascial incision for open entry.

14. **Peritoneal Entry.** A hemostat or finger is used to bluntly open the peritoneum, and the end of an S-shaped retractor is placed into the abdomen. The abdominal portion of the retractor is used to shield the underlying organs as a stitch of 0-gauge delayed-absorbable suture is place parallel on one side of the fascial opening (Fig. 41-28.12). This suture is not tied. This suturing step is repeated on the opposite fascial edge.

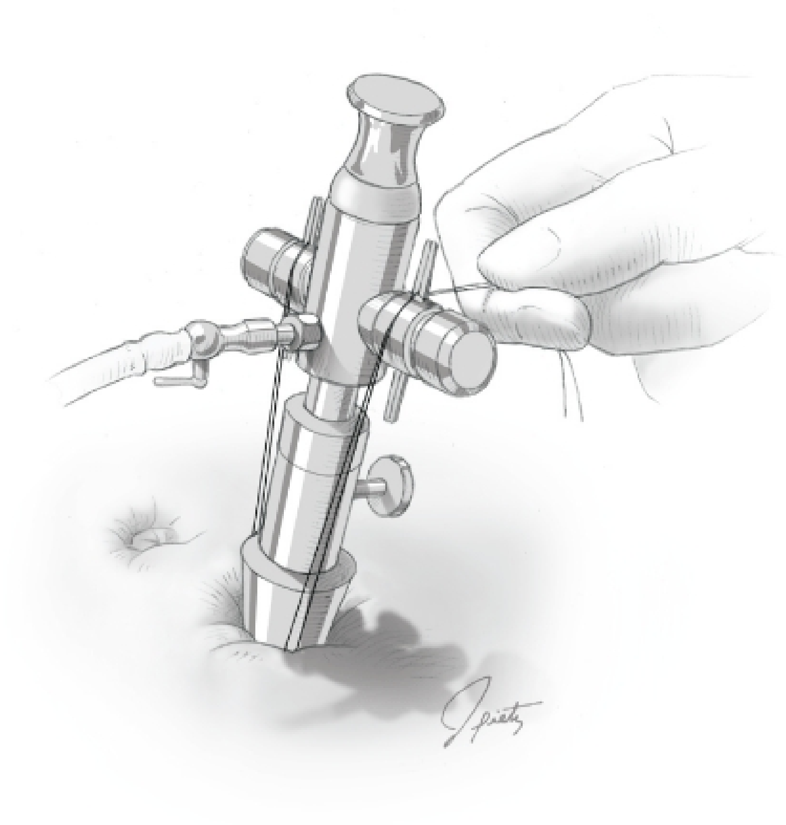
FIGURE 41-28.12



Peritoneal entry during open entry.

15. **Primary Trocar Placement with Open Entry.** The distal, blunt end of the trocar then is inserted into the incision. The fascial tag sutures are pulled firmly upward and threaded into the suture holders found on either side of the cannula's proximal end (Fig. 41-28.13). The blunt obturator is removed, and the laparoscope is threaded through the cannula.

FIGURE 41-28.13



Primary trocar placement with open entry.

16. **Secondary Operative Cannula Site Selection.** During laparoscopy, additional operative cannulas are needed to insert instruments into the abdomen. The number, location, and size of these cannulas will vary depending on the surgical instruments required for the laparoscopic procedure.

    The patient is placed in Trendelenburg position to aid displacement of bowel from the pelvis. Trocars are placed using direct laparoscopic visualization to minimize the puncture risk to anterior abdominal wall vessels or to the bladder. Typical cannula sites are displayed in Figure 41-28.1.

17. **Transillumination.** Within the anterior abdominal wall, the superficial and inferior "deep" epigastric arteries course parallel to the rectus abdominis muscles (see Fig. 38-3). Specific to avoiding puncture of the superifical epigastric vessels, transillumination of the anterior abdominal wall is useful. During this process, the laparoscope, within the abdominal cavity, is placed directly against the peritoneal surface of the anterior wall. The wall is illuminated, and the superficial epigastric arteries are seen as dark vessels traversing it.

18. **Inferior Epigastric Artery Indentification.** Unfortunately, the inferior epigastric arteries lie deep to the rectus abdominis muscle and are poorly seen with transillumination (Hurd, 1992). These arteries, however, can be seen by direct laparoscopic visualization in most cases (Hurd, 2003). Anatomic landmarks also can be used to avoid vessel puncture. For example, using results from cadaveric dissection, Epstein and co-workers (2004) noted that the main stem of the inferior epigastric artery can be avoided if trocars are inserted within the lateral third of the distance between the midline and anterosuperior iliac spine.

19. **Laparoscopic Procedures.** The indicated procedure then may be performed.

20. **Abdomen Deflation.** At completion of laparoscopy, the abdominal cavity is deflated. To prevent diaphragmatic irritation from retained CO_2 , manual pressure should be placed on the abdomen to help expel remaining gas.

21. **Trocar Removal at Surgery's End.** On completion of surgery, cannulas should be removed using laparoscopic visualization. This allows evaluation for bleeding from punctured vessels that may have been tamponaded by the cannula. Additionally, it prevents herniation of bowel or omentum up through the cannula track and into the anterior abdominal wall.

22. **Closed Entry Incision Closure.** Depending on their size, incisions may require deep fascial stitches. Lajer and co-workers (1997) recommended fascial closure to prevent incisional hernia formation whenever trocars measuring 10 mm or greater were used. Skin incisions are closed with a subcuticular stitch of 4-0 delayed-absorbable suture. Alternatively, the skin may be closed with cyanoacrylate tissue adhesive (Dermabond Topical Skin Adhesive, Ethicon, Somerville, NJ) or skin tape (Steri-Strip Elastic with Steri-Strip Compound Benzoin Tincture, 3M HealthCare, St. Paul, MN).

23. **Open Entry Incision Closure.** During removal of the Hasson trocar, sutures originally placed in the fascia are unthreaded from the trocar. Each of these sutures then is brought to the midline of the incision, and square knots are tied to close the fascial defect. The skin is reapproximated using a subcuticular suture with 4-0 delayed-absorbable suture (Hasson, 2000).

Postoperative

Depending on the procedure performed, most patients can be discharged home on the same day as surgery. For most, physical activities and diet can be resumed based on patient comfort.

41-29 LAPAROSCOPIC STERILIZATION

Approximately 700,000 tubal sterilization procedures are performed annually in the United States. About half of these follow pregnancy delivery or termination, but the others are performed independent of pregnancy and are termed *interval sterilization* (Westhoff, 2000). Most interval procedures are performed laparoscopically, and most commonly involve tubal occlusion by electrosurgical coagulation, by mechanical clips, by Silastic bands, or by suture ligation (Pati, 2000).

Preoperative

CONSENT

Tubal sterilization is a safe surgical procedure with few associated complications. In general, the risks of laparoscopic sterilization mirror those of laparoscopy, as discussed in Section 41-28, Laparoscopy. Rarely, case reports of clip migration to sites such as the bladder, uterine cavity, and anterior abdominal wall have been noted in the literature (Gooden, 1993; Kesby, 1997; Tan, 2004). Most ectopic clips are incidental findings with untoward patient effects, but less commonly, they can incite local foreign-body reactions.

In addition to surgical risks, contraceptive failure and pregnancy rates related to each procedure should be discussed with patients (see Chap. 5, Sterilization). Overall, these rates are low, and tubal sterilization is an effective method of contraception. For this reason, patients undergoing this procedure should be confident in their desires for permanent sterilization.

If pregnancy does occur, however, there is a greater risk of ectopic pregnancy. Bipolar coagulation has the highest risk for this complication compared with that of clips and bands (Peterson, 1996). Accordingly, amenorrhea following any sterilization procedure should prompt serum β-hCG testing to aid in identifying ectopic pregnancies.

Lastly, a small percentage of women experience regret following sterilization (see Chap. 5, Cautions). For this reason, prior to surgery, women should be counseled about the risk of regret and about alternative effective long-term contraceptive methods.

Intraoperative

Surgical Steps

1. **Anesthesia and Patient Positioning.** Most laparoscopic tubal sterilization procedures are performed using general anesthesia, although a few investigators have described microlaparoscopic procedures using local or regional analgesia (Siegle, 2005; Tiras, 2001).

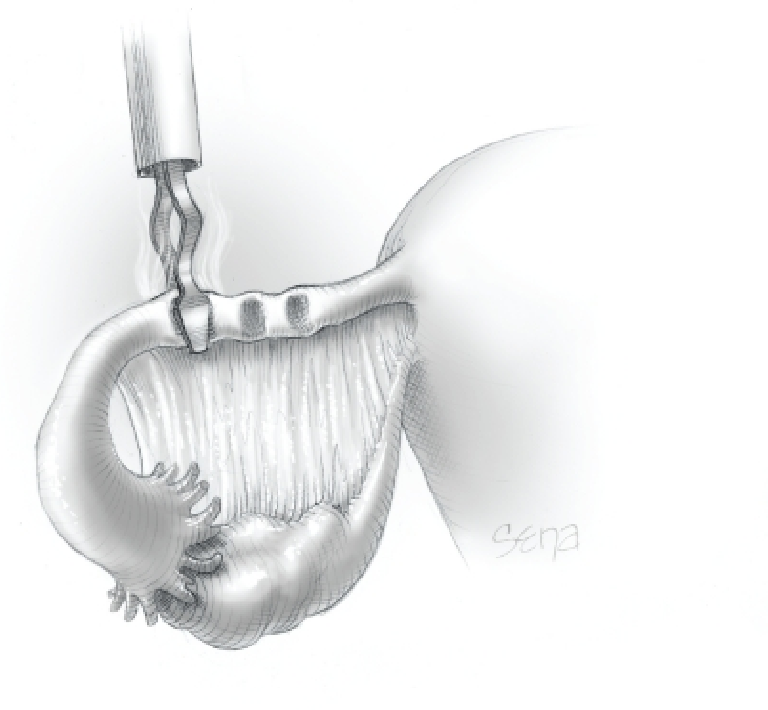
   In patients receiving general anesthesia, investigators also have evaluated the adjunctive use of several local analgesia techniques. Specific to sterilization procedures, 5 mL of a 0.25-percent or 0.5-percent bupivacaine solution from a needle and syringe may be dripped onto the serosal tubal surface prior to tubal occlusion (Brennan, 2004; Wrigley, 2000). Most studies comparing outcomes both with and without this topical analgesia have shown improvement in pain scores during the immediate postoperative period (30 minutes to 1 hour) but no overall differences in pain scores at later time intervals or total pain medication consumption.

   Alternatively, bupivacaine solutions have been delivered transcervically through balloon laparoscopic uterine manipulators into the fallopian tube lumen (see Fig. 41-28.5). In most evaluations, however, this method has proved ineffective in lessening postoperative pain (Ng, 2002; Schytte, 2003).

   The patient is positioned in the dorsal lithotomy position, and for all the procedures described, the initial steps of laparoscopic abdominal entry are performed as described in Section 41-28, Laparoscopy.

2. **Bipolar Electrosurgical Coagulation.** The fallopian tube is identified and grasped in the isthmic region at least 2 to 3 cm lateral to the cornua (Fig. 41-29.1). Placement here is important. Pressure from retrograde menstrual flow against a coagulated stump that has been placed too close to the cornua can increase the risk of stump recanalization and fistula formation. Leaving a 2- to 3-cm segment allows ample space for absorption of intrauterine fluid without creating excess pressure against the stump.

FIGURE 41-29.1



Source: Schorge JO, Schaffer JI, Halvorson LM, Hoffman BL, Bradshaw KD, Cunningham FG: *Williams Gynecology*: http://www.accessmedicine.com

Bipolar electrosurgical coagulation.

3. **Electrocoagulation.** The coagulating paddles of bipolar forceps should span the tube. Overextending their grasp may lead to partial coagulation of the mesosalpinx and incomplete coagulation of the entire tube width.

   Before current is applied, the tube is elevated slightly and pulled away from other adjacent structures to prevent thermal injury to those structures. As current is applied, the tube will swell, and fluid often bubbles and pops from the tissue. Current is delivered until the tube is completely desiccated. Failure to reach this endpoint has been linked with increased contraceptive failures (Soderstrom, 1989). Because visual inspection of a tube typically is inadequate to assess complete desiccation, an ammeter is incorporated with most bipolar generators. Water conducts current through tissues, and completely desiccated tissue therefore are unable to conduct current. Accordingly, current should be applied until zero current flow across the tube is registered by the ammeter. Then the tube is released.

   A second site that is lateral to but contiguous with the first coagulated segment is grasped and similarly coagulated. A total of two to three contiguous sites are serially coagulated. This occludes a total span of 3 cm along the length of the tube. Coagulation of shorter distances along the tube can lead to recanalization and contraceptive failure (Peterson, 1999). These steps then are repeated on the opposite fallopian tube.

   Occasionally, following coagulation, the tube may stick to the bipolar paddles. To free the tube, slowly open the paddles and gently twist the forceps paddles to the right and then the left.

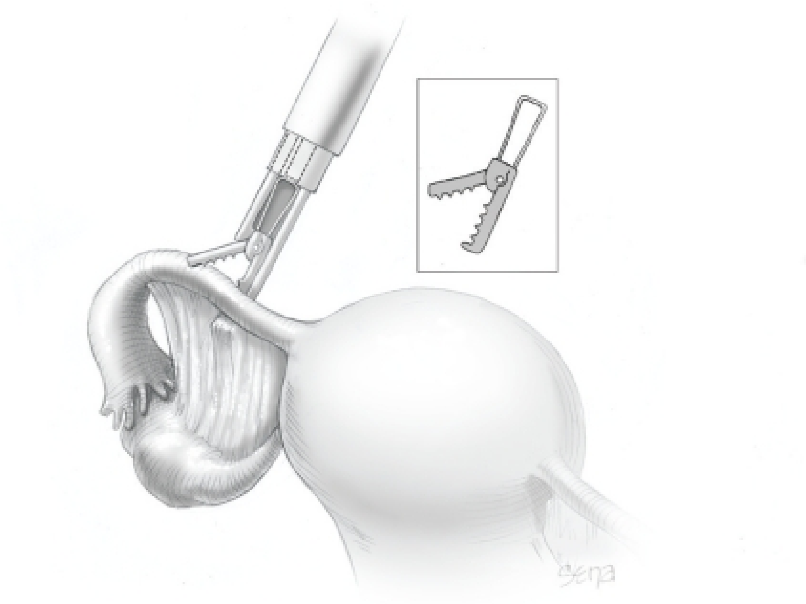
4. **Hulka Clip Application.** The plastic Hulka clip (Richard Wolf Medical Instruments Corporation, Vernon Hills, IL) is also generically known as a *spring clip* because of the metal spring that locks the clip into place during application.

5. **Clip Loading.** At the beginning of clip application, the trigger of the applicator is gently squeezed by the surgeon's thumb. This action advances the first arm of the applicator down and over the top of the clip. This closes the jaws of the clip to within 1 mm of each of other. This is an unlocked position yet allows the clip and applicator to be threaded down the laparoscopic cannula.

6. **Clip Application.** Once inside the abdomen, the applicator trigger is drawn backward, and the upper jaw of the clip reopens. The fallopian tube is grasped with atraumatic grasping forceps and outstretched horizontally and laterally. Concurrently, a uterine manipulator can be used to tilt the uterus laterally and in the opposite direction.

   Held within the applicator bracket, the clip is positioned across the narrow isthmic area of the tube, about 2 cm from the cornua, and perpendicular to the long axis of the tube (Fig. 41-29.2). The jaws are positioned around the tube in a manner that directs the tube deeply into the crux of the jaws. This aids in total occlusion of the tube as it is flattened across the base of the closing clip. Additionally, positioning of the distal tip of the applicator and clip should be such that when closed, the clip should incorporate a small portion of subjacent mesosalpinx.

FIGURE 41-29.2



Source: Schorge JO, Schaffer JI, Halvorson LM, Hoffman BL, Bradshaw KD, Cunningham FG: *Williams Gynecology*: http://www.accessmedicine.com

Hulka clip application.

7. **Clip Closure.** Once the applicator jaws are positioned appropriately, the thumb-action trigger is squeezed slowly to push forward the outer applicator arm and close the clip around the tube (Fig. 41-29.3). The clip application in inspected to ensure that it has encompassed the tube completely.

   If placement is deemed correct, the trigger is depressed fully. This forces the second arm forward against the butt of the clip's metal spring (Fig. 41-29.4). The band is pushed out and around the plastic frame of the clip to compress and lock the upper and lower clip jaws in place.

   One clip is placed on each tube. If a clip is misapplied, a second clip can be placed lateral to the first.

Hulka spring secured.

8. **Filshie Clip Application.** The titanium Filshie clip (Avalon Medical Corp, Williston, VT) is applied with the aid of a customized metal applicator that closes and locks the rim of the shorter upper jaw under the lip of the lower jaw (Fig. 41-29.5).

FIGURE 41-29.5

Filshie clip **A.** Single clip open. **B.** Closed clips around plastic tubing. (From Penfeld, 2000, with permission).

9. **Applicator Insertion.** At the beginning of clip application, a Filshie clip is held within its applicator and inserted through the laparoscopic cannula into the abdomen. A surgeon half closes the applicator's upper jaw to insert it and the clip through the laparoscopic cannula. Care must be taken not to grip the handle of the applicator too tightly because this may close and lock the clip prematurely (Penfield, 2000).

   Once the Filshie clip emerges through the cannula, the applicator is opened slowly. The jaw of the applicator has the potential to open quickly. This can result in the clip falling off the applicator and into the abdomen.

10. **Filshie Clip Placement.** After the clip is completely open, the clip and applicator are positioned with one jaw above and one below the tube. The entire width of the tube should lie across the base of the clip, and the distal hooked end of the lower jaw should be visible through the mesosalpinx.

11. **Filshie Clip Application.** Once satisfied that the clip is positioned correctly, the surgeon slowly squeezes the finger bar-spring handle to its full limit, back toward the handle backstop. With this action, the upper jaw of the clip is compressed slowly and locked under the hooked end of the lower jaw. This flattens the tube within the clip. The clip is released automatically from the applicator and locked onto the tube. These steps are repeated on the opposite fallopian tube. If there is any doubt about the clip placement, a second clip is applied correctly.

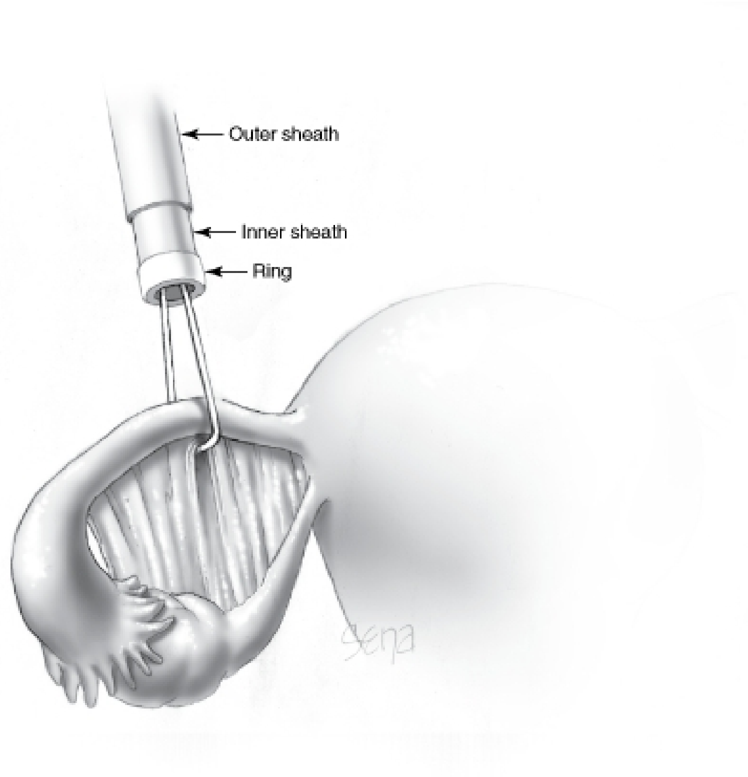
    Rarely, a fallopian tube may be transected by the clip. This usually is associated with a large fallopian tube that has been clipped too quickly. For completion, a clip is applied to both ends of the transected tube.

12. **Falope Ring (Silastic Band).** A Silastic Falope ring (ACMI, Southborough, MA) is applied with the aid of a customized metal applicator. In overview, applicator tongs draw a portion of tube up into an inner sheath, and an outer sheath then pushes a Silastic band off the inner sheath and onto the base of a loop of tube.

13. **Ring Loading.** Prior to its insertion into the abdomen, a Falope ring is stretched around the distal tip of the inner applicator sheath by means of a special ring loader and ring guide.

14. **Ring Placement.** Once inserted into the abdomen, the applicator's tongs are placed completely around the fallopian tube approximately 3 cm from the cornua, and they grasp the mesosalpinx directly at its attachment to the tube. This prevents excess mesosalpinx from being drawn into the inner sheath (Fig. 41-29.6).

FIGURE 41-29.6

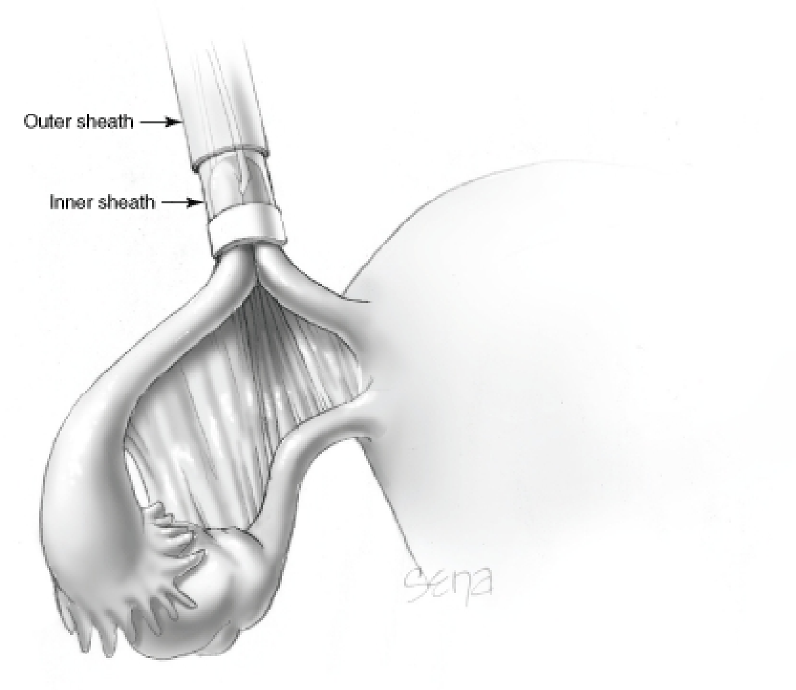


Falope ring applicator placement.

15. **Ring Application.** A trigger on the applicator retracts the tongs and draws a knuckle of tube approximately 1.5 cm into the inner sheath. The total length of tube contained within the inner sheath is 3 cm (Fig. 41-29.7).

    The outer sheath then is advanced toward the knuckle of the tube. This pushes the Silastic band off the inner sheath and onto the knuckle base (Fig. 41-29.8). The loop of tube will blanch from ischemia following band placement. These steps are repeated on the opposite fallopian tube.

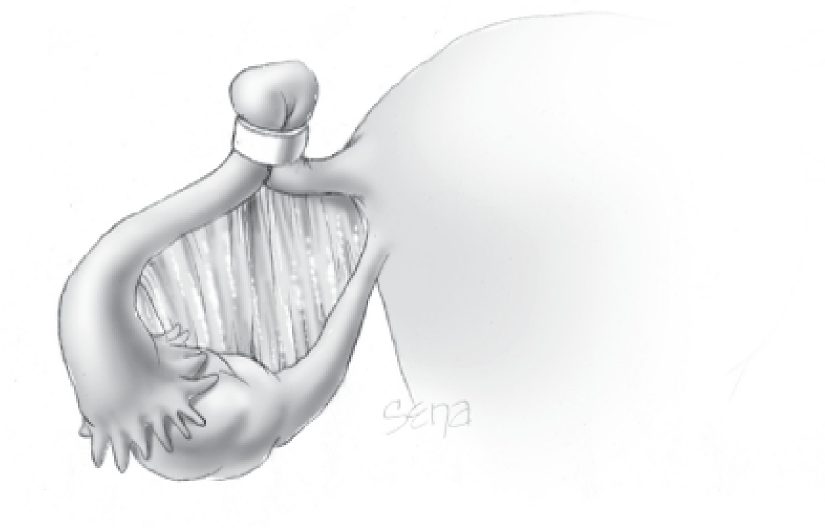
FIGURE 41-29.7



Source: Schorge JO, Schaffer JI, Halvorson LM, Hoffman BL, Bradshaw KD, Cunningham FG: *Williams Gynecology*: http://www.accessmedicine.com

Tube drawn into inner sheath.

FIGURE 41-29.8



Falope ring in place.

16. **Special Circumstances.** Tubal transection is uncommon, and a Falope ring can be applied to each of the divided segments. Vessels of the mesosalpinx can tear and bleed occasionally as the tongs and tube are drawn into the inner sheath. The Silastic band, once applied to the knuckle of the tube, will control bleeding in most instances, and use of electrosurgical coagulation to achieve hemostasis is needed infrequently.

17. **Pomeroy with Endoscopic Loop.** This procedure can be used as a sterilization technique but also has been used to excise fallopian tube ectopic pregnancies. A description and figures can be found in Section 41-30, Laparoscopic Salpingectomy.

Postoperative

Postoperatively, patients are given instructions similar to those following diagnostic laparoscopy.

41-30 LAPAROSCOPIC SALPINGECTOMY

For most women, laparoscopic management of ectopic pregnancy is the preferred approach. For some, laparoscopic salpingostomy is desired to preserve future fertility. In other cases, tubal rupture and damage or bleeding may not permit fallopian tube salvage. In these instances, laparoscopic salpingectomy is indicated.

In addition, salpingectomy also may be used to remove hydrosalpinges in women undergoing in vitro fertilization (IVF). Studies have shown improved pregnancy rates if such tubes have been excised (see Chap. 9, Hydrosalpinx). Less commonly, total salpingectomy can be used as a method of sterilization.

Preoperative

CONSENT

In addition to risks associated in general with laparoscopy, risks include conversion from a laparoscopic approach to laparotomy for procedure completion and injury to the ipsilateral ovary. Accordingly, the potential for oophorectomy should be discussed.

PATIENT PREPARATION

Because the risk of infection is low with both salpingectomy and laparoscopy, preoperative antibiotics typically are not required.

Intraoperative

Surgical Steps

1. **Anesthesia and Patient Positioning.** The patient is prepared and positioned for laparoscopic surgery.

2. **Abdominal Entry.** The abdomen is entered laparoscopically, and typically two or three secondary accessory trocar sites are used (see Section 41-28, Laparoscopy). Depending on the size of the ectopic, at least one 10-mm or larger accessory trocar may be necessary to allow specimen removal at surgery's end.

3. **Mesosalpingeal Incision.** The fallopian tube is lifted and held with an atraumatic grasping forceps. Kleppinger bipolar electrode forceps are placed across a proximal portion of the fallopian tube. A cutting current at 25 W should suffice (Fig. 41-30.1). When 0 amperage of flow is noted, scissors then can be used to cut the desiccated, blanched tube (Fig. 41-30.2).

   The Kleppinger forceps are next advanced across the proximal mesosalpinx. Similarly, current is applied, and the desiccated tissue is cut. This process moves serially from the proximal mesosalpinx to its distal extent under the tubal ampulla.

   Alternatively, the scissors themselves may be attached to current. In this technique, vessels within the mesosalpinx first are coagulated electrosurgically and then are cut. As the distal mesosalpinx is cut, the tube is freed.

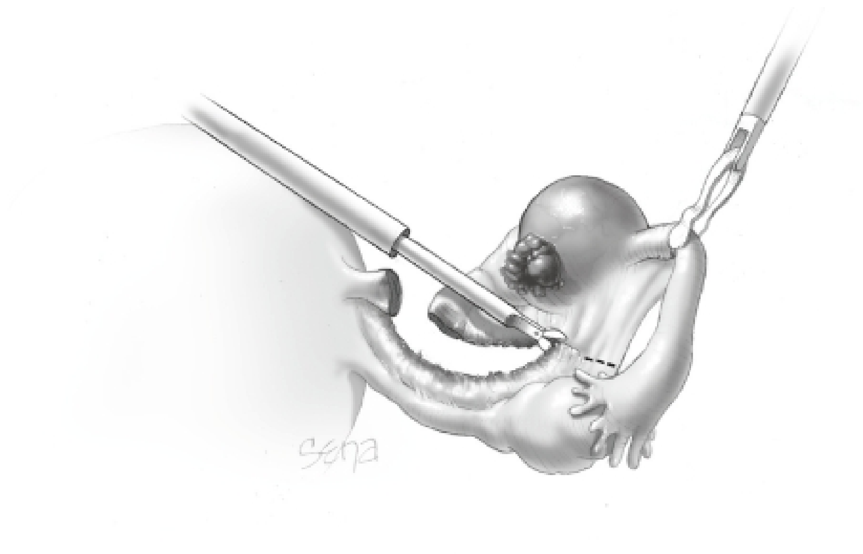
Fallopian tube desiccation.

FIGURE 41-30.2



Source: Schorge JO, Schaffer JI, Halvorson LM, Hoffman BL, Bradshaw KD, Cunningham FG: *Williams Gynecology*: http://www.accessmedicine.com

Mesosalpinx incision.

4. **Endoscopic Loop Ligation.** Alternatively, the vascular supply to the fallopian tube within the mesosalpinx can be ligated. Figure 41-30.3 shows an endoscopic suture loop encircling a knuckle of fallopian tube that contains the ectopic pregnancy. Two or three suture loops are placed sequentially, and the interposed portion of tube then is cut free with scissors (Fig. 41-30.4).

   Most tubal ectopic pregnancies are small and pliant. Accordingly, they can be held firmly by grasping forceps and drawn up into one of the accessory-site cannulas. The cannula, grasping forceps, and ectopic tissue then can be removed together.

   Larger tubal ectopic pregnancies may be placed in an endoscopic sac to prevent fragmentation as they are removed through the laparoscopic trocar sites (see Fig. 41-28.8). Alternatively, larger ectopic pregnancies can be divided with scissors or a laparoscopic morcellator and the smaller fragments removed.

Partial salpingectomy.

5. **Irrigation.** To prevent persistent trophoblastic tissue, the pelvis and abdomen should be irrigated and suctioned free of blood and tissue debris.

6. **Wound Closure.** Subsequent surgery completion steps should follow those of laparoscopy (see Section 41-28, Laparoscopy).

Postoperative

Guidelines for postoperative care mirror those of laparoscopic salpingostomy and can be found in Section 41-31, Laparoscopic Salpingostomy.

41-31 LAPAROSCOPIC SALPINGOSTOMY

For patients with ectopic pregnancy, laparoscopic salpingostomy offers the surgical advantages of laparoscopy and the opportunity to preserve fertility (see Chap 7, Salpingostomy). Accordingly, it should be considered one of the first-line treatments for those with ectopic pregnancies.

Preoperative

CONSENT

As noted earlier, treatment goals for ectopic pregnancy surgery include minimizing the effects of surgery, preventing persistent trophoblastic tissue, and preserving fertility in those so desiring it (see Section 41-25, Salpingectomy and Salpingostomy).

Surgical Approach

Laparoscopy offers patients significant advantages over laparotomy, including improved recovery and lower postoperative pain. The risks of this surgical approach are outlined in Section 41-28, Laparoscopy and should be included on any consent.

Bleeding

Because of the extreme vascularity of trophoblastic tissues, disruption of their vessels during removal of an ectopic pregnancy can lead to severe hemorrhage. The contractility of the tubal muscularis is minimal, and bleeding during salpingostomy must be controlled with external modalities such as electrosurgical coagulation. At times, bleeding may be extensive and persistent and necessitate salpingectomy. Prior to surgery, patients should be aware of this potential.

In an effort to improve hemostasis, vasoconstrictive agents such as vasopressin have been evaluated. Investigators describe diluting 20 IU of vasopressin in 20 to 50 mL of saline (Pouly, 1986; Ugur, 1996). The mesosalpinx then is infiltrated with approximately 10 mL of solution. Because of the potential systemic vasocontrictive effects of vasopressin, care must be taken to avoid intravascular injection. Additional complications and contraindications to its use are discussed in Section 41-18, Myomectomy. Benefits to vasopressin use include less frequent use of electrosurgery, shorter operating times, and lower conversion rates to laparotomy for surgery completion.

In an attempt to avoid the cardiovascular complications of vasopressin, Fedele and colleagues (1998) diluted 20 IU of oxytocin in 20 mL of saline and similarly injected the mesosalpinx. Oxytocin is purported to contract the smooth muscle fibers of the tube and cause vasoconstriction of mesosalpinx vessels. These researchers noted easier pregnancy enucleation, less bleeding, and less frequent use of electrosurgery.

Persistent Trophoblastic Tissue

During treatment of ectopic pregnancy, trophoblastic tissue can persist in as many as 3 to 20 percent of cases (see Chap. 7, Persistent Ectopic Pregnancy). Remnant implants typically involve the fallopian tube, but extratubal trophoblastic implants have been found on the omentum and on pelvic and abdominal peritoneal surfaces. Peritoneal implants typically measure 0.3 to 2.0 cm and appear as red-black nodules (Doss, 1998). Severe postoperative bleeding is the most serious complication of this persistent trophoblastic tissue (Giuliani, 1998).

The risk of persistent trophoblast tissue is highest following laparoscopic salpingostomy, especially in patients in whom small, early pregnancies are removed. In these pregnancies, a less well-defined cleavage plane between the interface of the invading trophoblast and the tubal implantation site develops. This may lead to a more difficult dissection and failure to completely removal all products of conception.

Preventive recommendations for this complication include irrigation and complete suctioning of the abdomen, limitation of the Trendelenburg position to limit blood and tissue flow to the upper abdomen, and use of endoscopic bags for removal of larger ectopic pregnancies (Ben-Arie, 2001).

Intraoperative

Surgical Steps

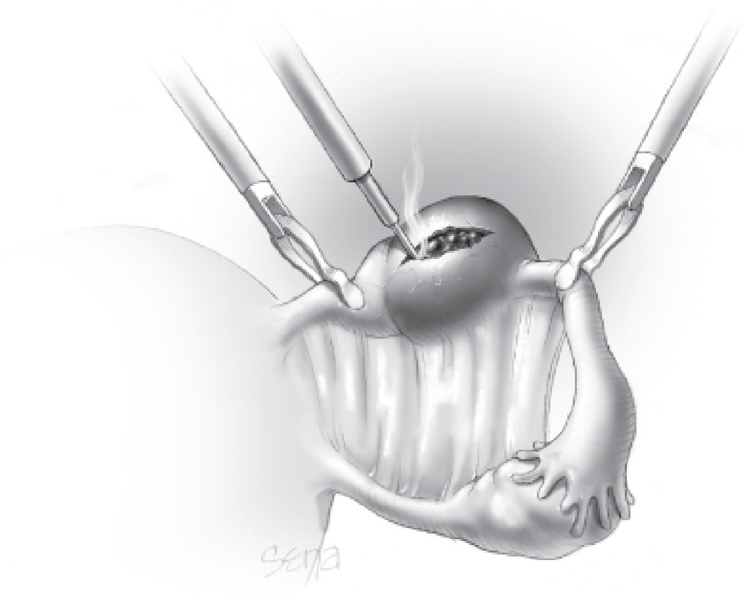
1. **Anesthesia and Patient Positioning.** The patient is prepared and positioned for laparoscopic surgery.

2. **Abdominal Entry.** The abdomen is entered laparoscopically, and typically two or three secondary accessory trocar sites are used (see Section 41-28, Laparoscopy). Depending on the size of the ectopic, at least one 10-mm or larger accessory trocar may be necessary to allow specimen removal at surgery's end.

3. **Salpingostomy.** The fallopian tube is lifted and held with atraumatic grasping forceps (Fig. 41-31.1). By means of a 22-gauge needle through one of the accessory trocar cannulas or separate abdominal insertion, a solution of vasopressin is injected into the mesosalpinx beneath the ectopic pregnancy.

   A unipolar needle tip electrode is set at a cutting voltage and used to create a 1- to 2-cm longitudinal incision. The incision should be positioned opposite the mesosalpinx and on the maximally distended portion of the tube that overlies the pregnancy. Laparoscopic scissors also may be used.

FIGURE 41-31.1

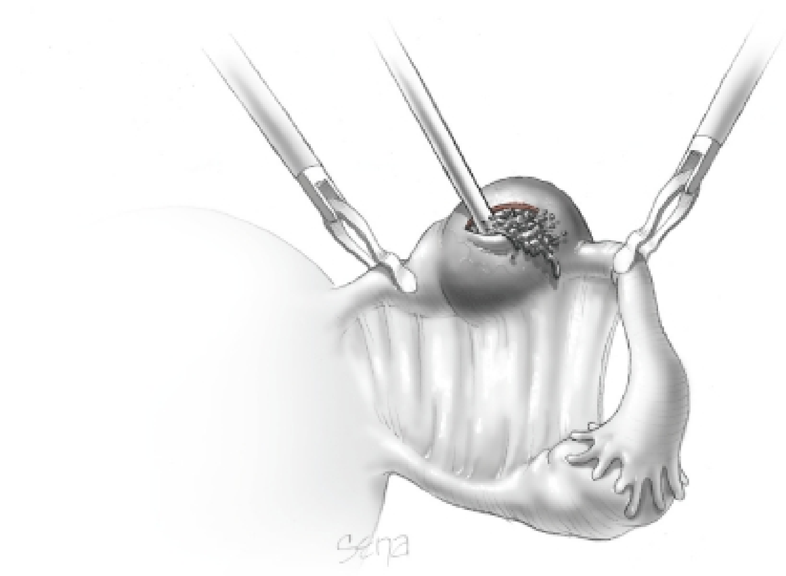


Source: Schorge JO, Schaffer JI, Halvorson LM, Hoffman BL, Bradshaw KD, Cunningham FG: *Williams Gynecology*: http://www.accessmedicine.com

Salpingostomy.

4. **Pregnancy Removal.** Atraumatic grasping forceps are used to hold one edge of the incision while a suction-irrigation probe tip is insinuated into the tissue plane between the tubal wall and ectopic pregnancy (Fig. 41-31.2). Hydrodissection is performed on one side of the tube and then the other. A combination of high-pressure hydrodissection and gentle blunt dissection with the suction irrigator is used to remove the entire product of conception from the tube. Alternatively, the pregnancy or its fragments may require extraction with the assistance of smooth grasping forceps.

FIGURE 41-31.2



Source: Schorge JO, Schaffer JI, Halvorson LM, Hoffman BL, Bradshaw KD, Cunningham FG: *Williams Gynecology*: http://www.accessmedicine.com

Hydrodissection.

5. **Hemostasis.** Bleeding points can be controlled with unipolar or bipolar electrosurgical coagulation. The tubal incision is left open to heal by secondary intention. Tulandi and Guralnick (1991) found no differences in subsequent fertility and adhesion formation between salpingostomy with or without tubal suturing.

6. **Specimen Extraction.** Most ectopic pregnancies are small and pliant. Accordingly, they can be held firmly by grasping forceps and drawn up into one of the accessory-site cannulas. The cannula, grasping forceps, and ectopic tissue then can be removed together.

   Larger ectopic pregnancies may be placed in an endoscopic sac to prevent fragmentation as they are removed through the laparoscopic trocar site (see Fig. 41-28.8).

7. **Irrigation.** To prevent persistent trophoblastic tissue postoperatively, the pelvis and abdomen should be irrigated and suctioned free of blood and tissue debris.

8. **Wound Closure.** Subsequent surgery completion steps should follow those of laparoscopy (see Section 41-28, Laparoscopy).

Postoperative

As with most laparoscopic surgeries, patients can resume preoperative diet and activity levels according to their comfort, typically within days. With end of any first-trimester pregnancy, the Rh status of the mother should be assessed. For Rh-negative patients, administration of 50 or 300 μg (1,500 IU) Rh_0 [D] immune globulin intramuscularly within 72 hours can minimize the risk of isoimmunization in future pregnancies.

To identify patients in whom trophoblastic tissue may persist, serial weekly serum β-hCG levels should be monitored (Seifer, 1997). Moreover, Spandorfer and associates (1997) compared serum β-hCG levels one day postoperatively with those drawn prior to surgery. They found a significantly lower percentage of persistent trophoblastic tissue if the β-hCG level fell more than 50 percent and no cases if the level declined by greater than 77 percent. During surveillance contraception should be used to avoid confusion between persistent trophoblastic tissue and a new pregnancy.

41-32 OVARIAN DRILLING

Ovarian drilling is a technique of puncturing the ovarian capsule with a laser beam or an electrosurgical needle using a laparoscopic approach. Similar to ovarian wedge resection, this procedure's end goal is to reduce the amount of androgen-producing tissue. Ovarian wedge resection, however, requires a laparotomy approach, and for best results, excision of one half to three fourths of the ovarian medulla (Halbe, 1972). As a result of the long capsular incision required for this degree of resection, infertility secondary to adhesions was found to complicate many postoperative courses (Buttram, 1975; Toaff, 1976). To minimize this risk and avoid the need for laparotomy, ovarian drilling techniques using laparoscopy were developed in the early 1980s.

Compared with medical management, ovarian drilling has lower rates of ovarian hyperstimulation syndrome (OHSS) and multifetal gestation. Disadvantages include the surgical risks of laparoscopy and the risk of pelvic adhesion formation (Donesky, 1995). For these reasons, ovarian drilling is viewed as a second-line therapy. It can be useful in patients who fail to ovulate with clomiphene citrate, are at risk for OHSS, or who desire to minimize their risk for multifetal gestation. An additional discussion of this procedure's advantages, disadvantages, and indications can be found in Chapter 20, Ovarian Drilling.

Preoperative

CONSENT

Relatively few complications arise immediately after ovarian drilling. Hemorrhage, infection, and thermal bowel injury are infrequent. Similarly, ovarian atrophy following drilling is rare but has been reported (Dabirashrafi, 1989).

Adhesion formation following this procedure, however, is common. Most of these adhesions at second-look laparoscopy typically have been graded as minimal or mild (GÃ¼rgan, 1991). Moreover, researchers have described only a minimal, if any, impact of these adhesions on fertility (GÃ¼rgan, 1992; Naether, 1993). The risk of infertility secondary to adhesive disease, however, should be discussed with the patient prior to surgery.

Intraoperative

INSTRUMENTS

Ovarian drilling has been described using monopolar or bipolar electrosurgery or using carbon dioxide, argon, or Nd-YAG laser. Currently, no studies support the superiority of one modality (Strowitzki, 2005).

NUMBER OF OVARIAN PUNCTURES

Punctures into the ovarian capsule typically are 2 to 4 mm wide and 4 to 10 mm deep. Although techniques using as many as few as 4 or as many as 40 punctures per ovary have been described, there are a few studies that have investigated the optimal number of punctures (Farquhar, 2004). For example, Malkawi and Qublan (2005) showed that 5 punctures per ovary compared with 10 resulted in equally improved pregnancy rates and similarly low rates of postprocedural OHSS and multifetal gestation.

Surgical Steps

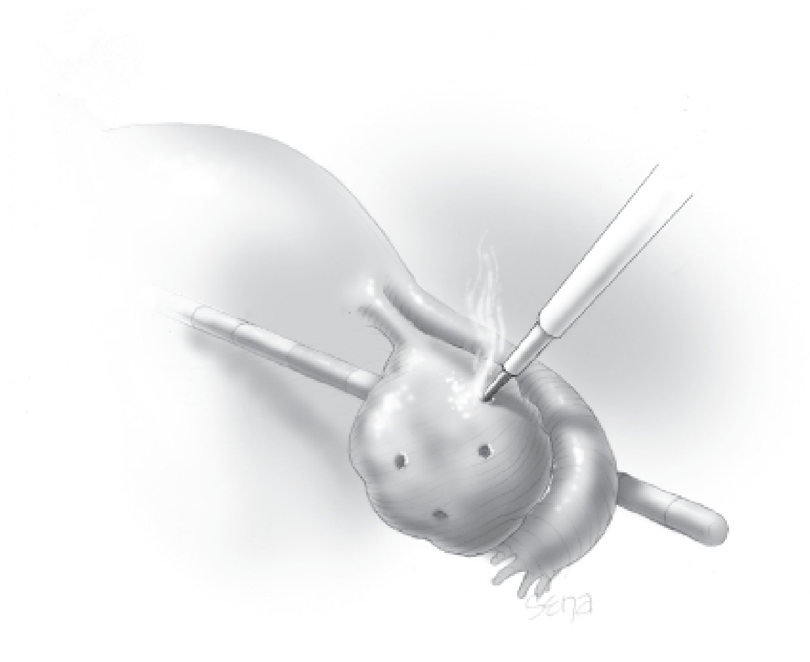
1. **Anesthesia and Patient Positioning.** Patient positioning and anesthesia mirror that for other laparoscopic procedures (see Section 41-28, Laparoscopy).

2. **Abdominal Entry.** Three incisions are used for this laparoscopic procedure. In addition to an infraumbilical incision, two bilateral lower abdominal incisions are made (see Fig. 41-28.1). These incisions serve as entry sites for the electrosurgical needle tip and blunt manipulating probe.

3. **Ovarian Drilling.** The ovary is elevated with a blunt probe. The electrosurgical current is set at 30 to 60 W cutting mode. An electrosurgical needle tip is used to puncture the ovary perpendicular to the capsular surface and to pierce the follicular cysts that are characteristic of PCOS. Three to five punctures are placed symmetrically on the anterior surface of the ovary (Fig. 41-32.1). Drilling is avoided on the lateral surfaces of the ovaries to minimize adhesions and is avoided at the ovarian hilus to limit bleeding risk. The needle is inserted to a depth of 4 to 10 mm. Electric current is applied for 3 to 4 seconds.

   The surface of the ovary can be irrigated with saline or lactated Ringer's solution to cool the capsular surface (Strowitski, 2005).

FIGURE 41-32.1



Source: Schorge JO, Schaffer JI, Halvorson LM, Hoffman BL, Bradshaw KD, Cunningham FG: *Williams Gynecology*: http://www.accessmedicine.com

Ovarian drilling.

4. **Adhesion Barriers.** Because of the risk for adhesion formation, some investigators have used adhesion barrier products following ovarian drilling. Greenblatt and Casper (1993), however, showed no improvement in adhesion prevention following this procedure using Interceed Adhesion Barrier (Ethicon, Summerville, NJ). No other studies have addressed the efficacy of other adhesion prevention products.

Postoperative

Postoperatively, patients are given instructions similar to those following diagnostic laparoscopy.

41-33 LAPAROSCOPIC OVARIAN CYSTECTOMY

Many studies have attested to the efficacy and safety of laparoscopic cystectomy for the management of ovarian cysts. Moreover, because of associated benefits, such as shorter hospital stay, quicker patient recovery, and lower rates of postoperative pain, infection, and adhesions, a laparoscopic technique is advocated by many as the preferred approach in women with ovarian cysts and a low risk of malignancy (see Chap. 9, Laparoscopy).

Preoperative

PATIENT EVALUATION

Sonography

Sonography is the primary tool used to diagnose ovarian pathology, and the sonographic characteristics of a cyst aid in determining preoperatively the malignant potential of a given lesion. In patients with indeterminate ovarian cysts following sonography, magnetic resonance (MR) imaging has been shown to enhance discrimination.

Tumor Markers

Serum cancer antigen 125 (CA125) levels typically are drawn preoperatively in postmenopausal patients and in any women whose tumor displays other risk factors for malignancy (see Chap. 9, Observation). Additionally, serum alpha-fetoprotein (AFP), lactate dehydrogenase (LDH), inhibin, and β-hCG levels may be measured to exclude other ovarian neoplasms (see Chap. 36, Laboratory Testing).

CONSENT

Prior to surgery, patients should be informed of the unique complications associated with laparoscopy. Specific to ovarian cystectomy, the risks of oophorectomy due to bleeding or extreme ovarian damage should be discussed. Obviously, because many cysts are removed because of concerns for potential malignancy, patients should be aware of the steps involved in the surgical staging of ovarian cancer.

PATIENT PREPARATION

Because of low rates of pelvic and wound infection follow ovarian cystectomy and laparoscopy, antibiotic prophylaxis typically is not required. Bowel preparation is not usually required but may be considered if extensive bowel adhesions are suspected.

Intraoperative

Surgical Steps

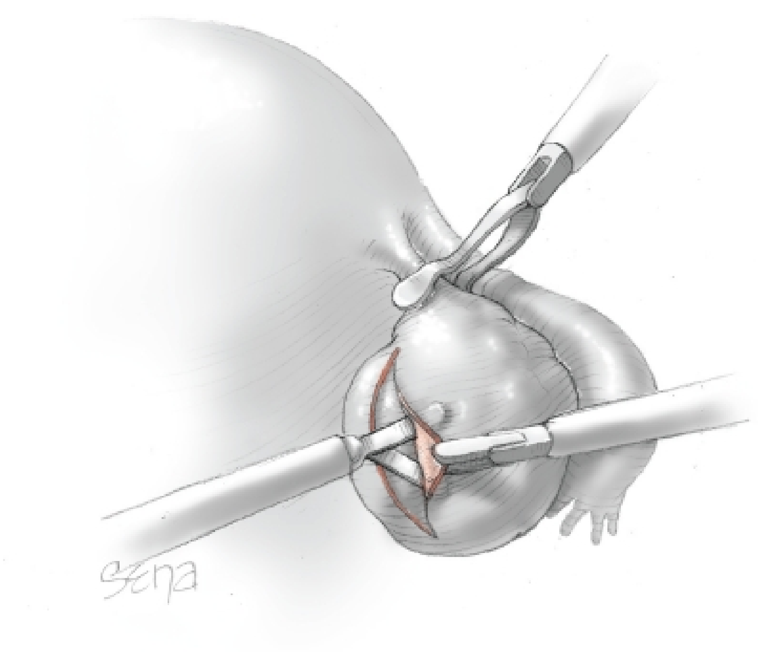
1. **Anesthesia and Patient Positioning.** As with most laparoscopic procedures, a patient should be placed in the dorsal lithotomy position after adequate general anesthesia has been delivered. In anticipation of possible hysterectomy as a part of ovarian cancer staging, the vagina and abdomen should be surgically prepared. A Foley catheter is placed to avoid operative field obstruction by or injury to a full bladder. The patient then is draped to allow sterile access to the vagina and abdomen.

2. **Abdominal Entry.** Primary and secondary trocar sites are placed as described in Section 41-28, Laparoscopy. Typically, two or three accessory trocar sites are required.

   Once the abdomen is entered, the pelvis and upper abdomen should be inspected for signs of malignancy, such as ascites and peritoneal implants. Cellular washings from these areas should be obtained and saved until frozen-section analysis of the specimen has excluded malignancy. Similarly, identified peritoneal implants should be biopsied and sent for frozen-section analysis.

3. **Ovarian Incision.** A blunt probe is place under the utero-ovarian ligament and posterior ovarian surface to elevate the ovary. An atraumatic grasping forceps then steadies the ovary, and the blunt probe is removed (Fig. 41-33.1). A unipolar needle tip electrode set at a cutting voltage is used to incise the ovarian capsule that overlies the cyst. Care is taken to avoid puncture of the cyst.

FIGURE 41-33.1



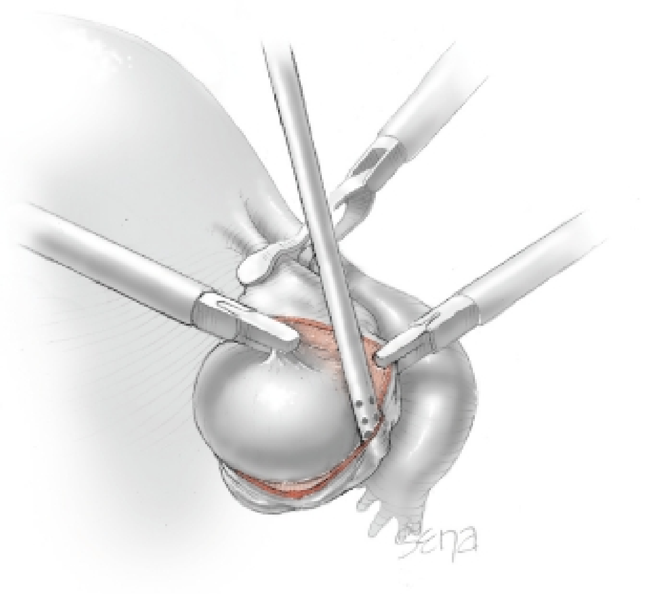
Source: Schorge JO, Schaffer JI, Halvorson LM, Hoffman BL, Bradshaw KD, Cunningham FG: *Williams Gynecology*: http://www.accessmedicine.com

Ovarian incision.

4. **Cyst Dissection.** A space between the ovary and cyst wall is created using blunt forceps or dissecting scissors (see Fig. 41-33.1). Atraumatic grasping forceps are used to hold one edge of the incision while a blunt probe or suction-irrigation probe tip is insinuated in the tissue plane between the ovarian capsule and cyst wall (Fig. 41-33.2).

   Blunt or hydrodissection is performed on one side of the cyst and then the other. Depending on the adherence of the cyst to its surrounding ovarian tissue, cystectomy at times may require sharp dissection with scissors. During dissection, points of bleeding may be coagulated, or isolated vessels may be grasped and coagulated.

FIGURE 41-33.2



Source: Schorge JO, Schaffer JI, Halvorson LM, Hoffman BL, Bradshaw KD, Cunningham FG: *Williams Gynecology*: http://www.accessmedicine.com

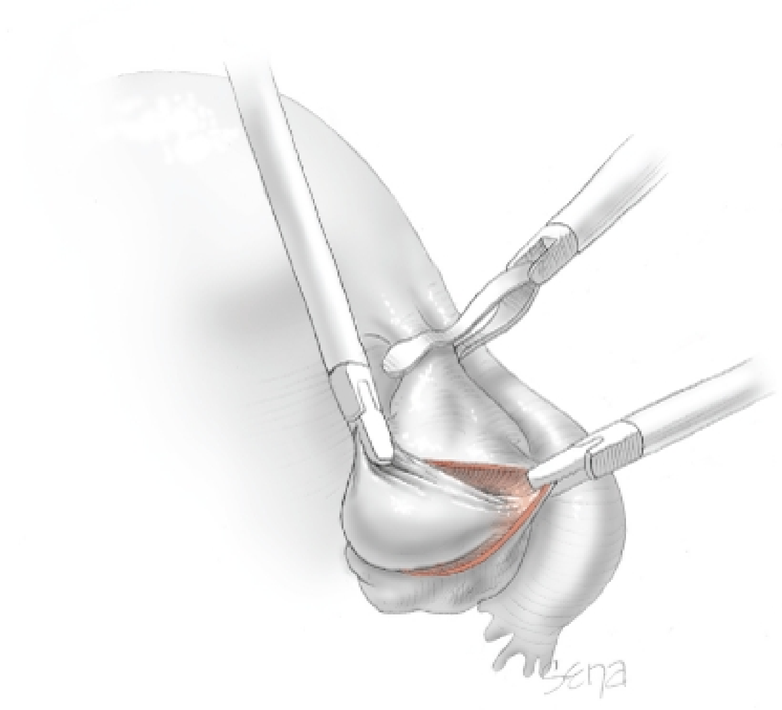
Cyst dissection.

5. **Cyst Removal.** Following enucleation from the ovary, the cyst is placed into an endoscopic bag (see Fig. 41-28.8). The opening of the sac is closed and brought up to the anterior abdominal wall. Depending on its size, the cyst and endoscopic bag may be removed in toto through one of the secondary accessory trocar sites. In this setting, the laparoscopic cannula is removed first, followed by the cyst contained within the sac.

   Alternatively, with larger cysts, the cannula is removed, and the entire pursed opening of the bag is drawn up through the trocar incision and fanned out onto the skin surface. The open edges of the bag are pulled upward to lift and press the cyst up against the incision. A needle tip then is directed into the sac and pierces the cyst. An attached syringe is used to aspirate the contents. Any stray fluid is retained by the endoscopic sac. The endoscopic sac and decompressed cyst wall then are removed together through the incision.

6. **Cyst Rupture.** Not uncommonly during the dissection of the cyst away from the ovary, the cyst will rupture. The cyst wall then is removed using a "stripping" technique (Fig. 41-33.3). The edge of the ovarian capsule is held with grasping forceps while the collapsed cyst is grasped with a second pair. The grasping forceps then strip the cyst wall away from the underlying ovarian stroma (Mahdavi, 2004). Histologically, Muzii and colleagues (2002) showed that this technique in nonendometriotic lesions spared ovarian tissue and did not strip away normal ovarian tissue and follicles.

FIGURE 41-33.3



Source: Schorge JO, Schaffer JI, Halvorson LM, Hoffman BL, Bradshaw KD, Cunningham FG: *Williams Gynecology*: http://www.accessmedicine.com

Cyst wall removal.

7. **Ovary Closure.** Because of increased difficulty and time associated with laparoscopic suturing, the ovarian capsule is not sutured closed following cyst removal. Several studies have shown that leaving the capsule open does not lead to increased adhesion formation (Marana, 1991; Wiskind, 1991).

8. **Wound Closure.** The specimen is submitted in most cases for immediate frozen-section analysis. If benign findings are noted, then steps toward surgical closure begin. If malignancy is found, then surgical staging via laparotomy should ensue (see Chap. 35, Surgical Staging).

   The finishing laparoscopic steps are found in Section 41-28, Laparoscopy.

Postoperative

Following laparoscopic ovarian cystectomy, instructions similar to those for general laparoscopy are given.

41-34 LAPAROSCOPIC SALPINGO-OOPHORECTOMY

Laparoscopy can be used to safely remove many adnexa and in most cases offers a faster recovery and less postoperative pain than laparotomy. As discussed in Chapter 9, Laparoscopy, indications for adnexectomy vary but may include torsion, ovarian cyst rupture, suspicion of ovarian malignancy, and symptomatic ovarian remnant. In addition, prophylactic oophorectomy is considered often in women with or at risk for cancers involving the breast, ovary, and colon (see Chap. 35, Prophylactic Surgery). However, there are clinical settings in which laparotomy is indicated, such as when the suspicion of cancer is high, extensive pelvic adhesions are anticipated, and ovarian masses are large.

Preoperative

PATIENT EVALUATION

Salpingo-oophorectomy typically is performed to remove ovarian pathology, and sonography is the primary tool used for diagnosis. In patients in whom anatomy may be unclear, magnetic resonance (MR) imaging may add additional information. As discussed in Chapters 35, Imaging and 36, tumor markers may be drawn prior to surgery if malignancy is suspected.

CONSENT

Prior to surgery, patients should be informed of the unique complications associated with laparoscopy. Specific to salpingo-oophorectomy, the risk of ureteral injury should be discussed. Obviously, because many adnexa are removed due to concerns of potential malignancy, patients should be familiar with the steps involved in the surgical staging of ovarian cancer (see Chap. 35, Surgical Staging).

PATIENT PREPARATION

Unless an ovarian abscess is identified, antibiotic prophylaxis is generally not required and is administered according to the preference of the surgeon.

Intraoperative

Surgical Steps

1. **Anesthesia and Patient Positioning.** As with most laparoscopic procedures, the patient should be placed in the dorsal lithotomy position after adequate general anesthesia has been delivered. Because of possible hysterectomy as a part of ovarian cancer staging, the vagina and abdomen are surgically prepared, and a Foley catheter is placed.

2. **Trocar and Laparoscope Insertion.** Primary and secondary trocar sites are placed as described in Section 41-28, Laparoscopy. Typically, two or three accessory trocar sites are required.

3. **Pelvic Inspection and Washings.** Once abdominal access has been completed, the pelvis and upper abdomen should be inspected for signs of malignancy. Cell washings from these areas can be obtained using a laparoscopic suction-irrigating tool and should be saved until frozen-section analysis of the specimen has excluded malignancy. Similarly, identified suspicious peritoneal implants are biopsied and sent for frozen-section analysis. If adhesions are present, they are lysed to restore normal anatomy for the procedure.

4. **Ureter Location.** The ureter lies close to the infundibulopelvic (IP) ligament, and its course should be noted. If the location of the ureter is not clear, the peritoneum lateral to the ureter is incised (Fig. 41-34.1) The medial peritoneal leaf of the broad ligament is elevated and placed on traction. If the ureter is not immediately seen, then a blunt probe or suction tip is used in a sweeping motion from top to bottom along the medial peritoneal leaf to identify the ureter.

FIGURE 41-34.1

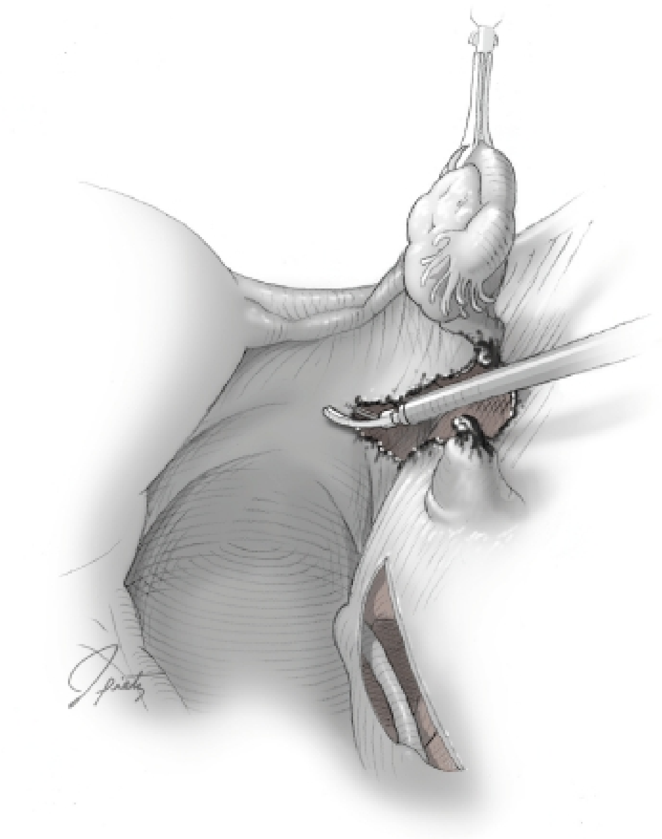
Source: Schorge JO, Schaffer JI, Halvorson LM, Hoffman BL, Bradshaw KD, Cunningham FG: *Williams Gynecology*: http://www.accessmedicine.com

Infundibulopelvic ligament coagulation.

5. **Infundibulopelvic Ligament Coagu-lation.** Ligation of the ovarian vessels within the IP ligament can be completed with endoscopic loop ligatures, electrosurgical coagulating devices, harmonic scalpel, or stapler depending on the preference of the surgeon Fig. 41-34.1. Once these vessels are occluded, the IP is severed proximally.

6. **Opening of the broad ligament.** After transection of the IP, incision of the broad ligament's posterior leaf is extended medially (Fig. 41-34.2).

FIGURE 41-34.2

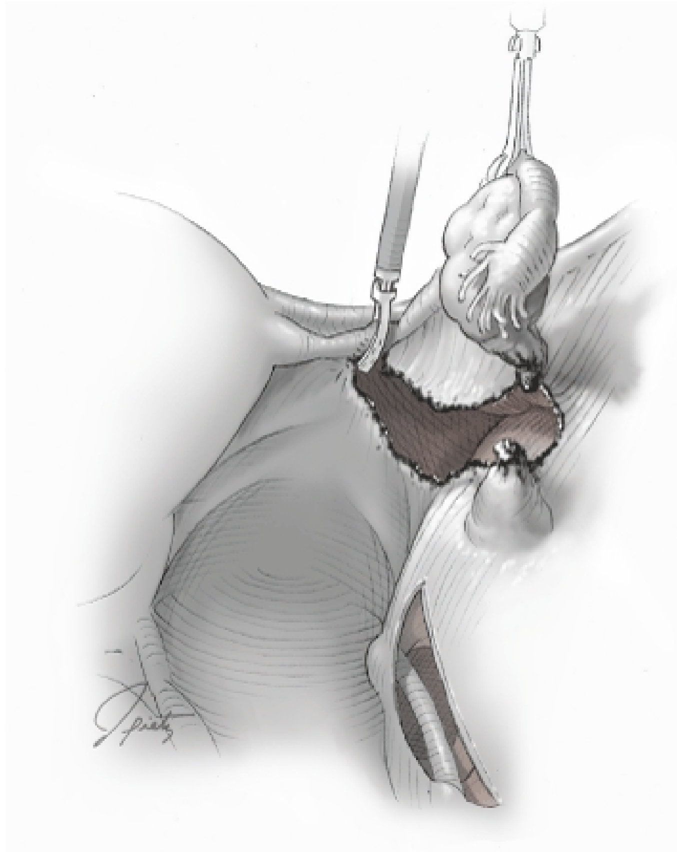


Source: Schorge JO, Schaffer JI, Halvorson LM, Hoffman BL, Bradshaw KD, Cunningham FG: *Williams Gynecology*: http://www.accessmedicine.com

Opening of the broad ligament.

7. **Utero-ovarian Ligament Coagulation.** The utero-ovarian ligament, proximal fallopian tube, and round ligament are identified posterior to the round ligament. Similarly to the IP, these may be coagulated, stapled, or ligated (Fig. 41-34.3). Distal to this occlusion, the utero-ovarian ligament and fallopian tube are transected, and the adnexa is freed.

FIGURE 41-34.3



Source: Schorge JO, Schaffer JI, Halvorson LM, Hoffman BL, Bradshaw KD, Cunningham FG: *Williams Gynecology*: http://www.accessmedicine.com

Fallopian tube and utero-ovarian ligament coagulation.

8. **Adnexa Removal.** A number of endoscopic bags are available for tissue removal (see Fig. 41-28.8). The specimen is dropped into the sac, which is closed and brought up to the anterior abdominal wall. Depending on its size, the adnexa and endoscopic bag may be removed in toto through one of the secondary accessory trocar sites. In this setting, the laparoscopic cannula is removed first, followed by the specimen contained within the sac.

   Alternatively, with larger cystic ovaries, the cannula is removed, and the entire pursed opening of the bag is drawn up through the trocar incision and fanned out onto the skin surface. The open edges of the bag are pulled upward to lift and press the ovary against the incision. A needle tip is directed into the trocar incision. The ovary is pierced, and aspiration drainage is completed by an attached syringe. Any stray fluid is retained by the endoscopic sac. The sac and decompressed adnexa then are removed together through the incision.

9. **Wound Closure.** If malignancy is suspected, the specimen is submitted for immediate frozen-section analysis. If benign findings are noted, then steps toward surgical closure begin as indicated in Section 41-28, Laparoscopy. If malignancy is found, then surgical staging via laparotomy should ensue.

Postoperative

Advantages to laparoscopy include a rapid return to normal diet and activities and postoperative complication rates are low. If both

adnexa are removed, then hormone-replacement therapy is considered in appropriate candidates (see Chap. 22, Current Approach to Hormone Replacement Administration).

41-35 HYSTEROSCOPY

Hysteroscopy allows an endoscopic view of the endometrial cavity and tubal ostia for both the diagnosis and operative treatment of intrauterine pathology. During the last two decades, the role of hysteroscopy in modern gynecology has expanded rapidly with development of more effective hysteroscopic instruments and smaller endoscopes.

Indications for hysteroscopy vary and include evaluation and in some cases, treatment of infertility, recurrent miscarriage, abnormal uterine bleeding, amenorrhea, and retained foreign bodies. With hysteroscopic techniques, abnormal bleeding can be treated with endometrial ablation, polypectomy, or submucous myomectomy. Infertility may be improved with incision of intrauterine adhesions or septa. Additionally, obstructed tubal ostia may be unblocked or dilated. Alternatively, for those seeking sterilization, tubal occlusion devices can serve as an effective and safe method of contraception.

Preoperative

PATIENT EVALUATION

Because the indications for hysteroscopy are varied, patient evaluations for specific disorders are discussed in their respective chapters. However, pregnancy is an absolute contraindication to hysteroscopy and should be excluded with serum or urine β-hCG testing prior to surgery. In addition, cervicitis or pelvic infection should be treated prior to hysteroscopy, and screening for *Neisseria gonorrhoeae* and *Chlamydia trachomatis* is warranted in those with risk factors (see Chap. 1, Ovarian Cancer). For those with abnormal bleeding and significant risks for endometrial cancer, preoperative endometrial pipelle sampling is reasonable because seeding of the peritoneal cavity with cancer cells has been noted following hysteroscopy.

If diagnostic hysteroscopy is planned to locate and remove a foreign body, preoperative imaging, usually with transvaginal sonography, is recommended. For example, in some cases, an intrauterine device (IUD) or retained fetal bone may have perforated the uterine wall, lie predominantly outside the uterus, and thus be best removed by laparoscopy.

CONSENT

The risk of complications for women undergoing hysteroscopy is low and is cited at less than 1 to 3 percent (Hulka, 1993; Jansen, 2000; Propst, 2000). Complications are similar to those associated with dilatation and curettage and include uterine perforation, inability to sufficiently dilate the cervix, hemorrhage, cervical laceration, and postoperative endometritis. In addition, because either gas or liquid medium is required to distend the endometrial cavity during hysteroscopy, gas venous embolism and excessive intravascular fluid absorption are risks, as discussed later. In general, the risk of complication increases with the length and complexity of the procedure planned.

In the event of uterine perforation during hysteroscopy, diagnostic laparoscopy often is warranted for evaluation of the surrounding pelvic organs. Thus, patients should be additionally consented and aware of the possible need for laparoscopy.

PATIENT PREPARATION

Endometrial Thickness

In premenopausal women, hysteroscopy ideally is performed in the early proliferative phase of the menstrual cycle, when the endometrium is relatively thin. This allows small masses to be identified and removed easily. Alternatively, agents that induce endometrial atrophy such as progestins, combination oral contraceptives, danazol, and gonadotropin-releasing hormone (GnRH) agonists have been administered individually prior to anticipated surgery. Although these effectively thin the endometrium, many of these agents have disadvantages, including expense, adverse side effects, and surgical delay while atrophy ensues.

Cervical Dilatation

For operative hysteroscopy, dilatation of the cervix typically is required to insert an 8- to 10-mm hysteroscope or resectoscope. To minimize the risk of bleeding that may obscure the operative view and to lower the risk of uterine perforation, laminaria tents may be placed the day before surgery, as described in Section 41-16, Sharp Dilatation and Curettage. Alternatively, 100 μg misoprostol

(Cytotec, Pfizer, New York, NY), a synthetic prostaglandin E_1 analogue, may be administered orally the night before and again the morning of surgery to aid cervical softening.

Intraoperative

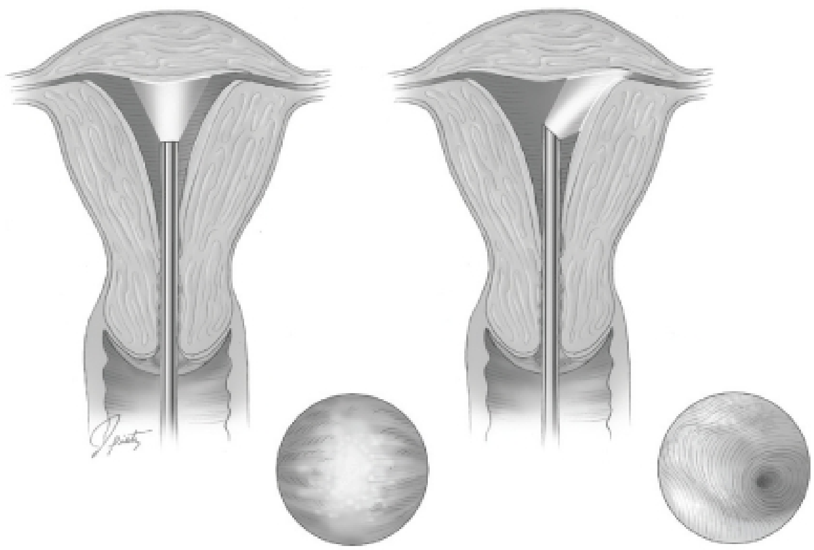
INSTRUMENTS

Hysteroscopy requires a hysteroscope, light source, uterine distention medium, and in many cases a video camera system.

Rigid Hysteroscope

Most hysteroscopes consists of an optical telescope with a diameter of 3 to 4 mm surrounded by an outer sheath. Individual endoscopes offers specific angles of view, and although 0- through 30-degree angles are available, 0- or 12-degree hysteroscopes allow the easiest orientation within the uterine cavity for most procedures (Fig. 41-35.1).

FIGURE 41-35.1

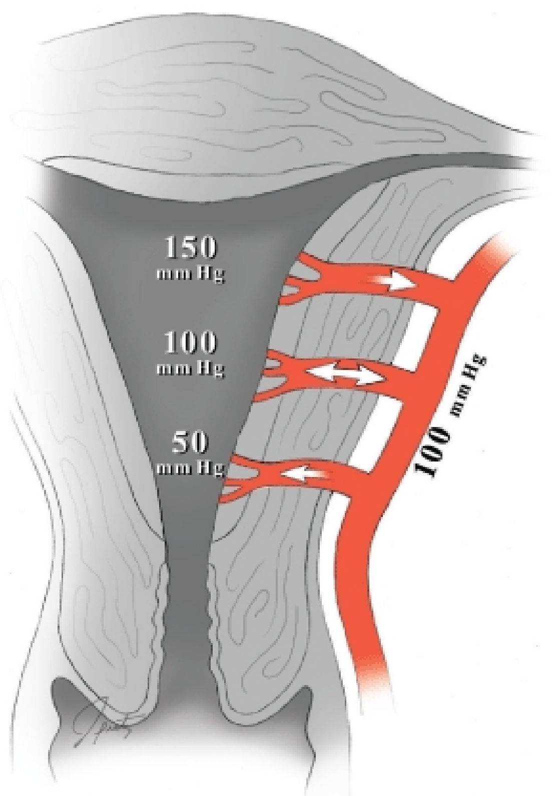


Source: Schorge JO, Schaffer JI, Halvorson LM, Hoffman BL, Bradshaw KD, Cunningham FG: *Williams Gynecology*: http://www.accessmedicine.com

Hysteroscopic views.

The outer sheath also offers variable features. It may be constructed to allow either unidirectional or continuous flow of distending media and may contain one, two, or no operative ports for instruments. Sheaths that allow continuous flow, that is, inflow and outflow circulation of the distention medium, are most valuable in patients in whom bleeding or large fluid volume deficits are a potential (Fig. 41-35.2). This circulation helps to clear blood from the operative field and assists with fluid volume deficit calculation. Volume deficits are calculated by the amount of distending media delivered subtracted by the amount returned through collection.

FIGURE 41-35.2



Distention medium flow varies depending on intrauterine pressure.

Resectoscope

If resection of intrauterine tissues is planned, then a resectoscope may be used. This tool consists of inner and outer sheaths. The inner sheath houses a 3- to 4-mm telescope and a channel for fluid medium inflow, whereas the 8- to 10-mm outer sheath allows fluid egress from the uterus through a series of small holes near the sheath's distal end. By means of a spring mechanism, the resection loop can be extended and then retracted to shave off contacted tissues.

Flexible Hysteroscope

Flexible hysteroscopes are available that have tips that can deflect over a range of 120 to 160 degrees. Although their optical view is less clear than that with rigid hysteroscopes, they offer surgeons the ease of maneuvering within irregularly shaped endometrial cavities.

Distention Media

Because the anterior and posterior uterine walls lie in apposition, a distention medium is required to expand the endometrial cavity for viewing. Media include carbon dioxide (CO_2), saline, and low-viscous fluids such as sorbitol, mannitol, and glycine solutions (Table 41-35.1). Each group has distinct advantages and properties. To expand the cavity, intrauterine pressures of these media must reach 45 to 80 mm Hg (Tulandi, 1999). Rarely is more than 100 mm Hg required. Moreover, because for most women mean arterial pressure approximates 100 mm Hg, higher pressures can result in increased intravasation of medium into the patient's circulation and fluid volume overload (Fig. 41-35.3).

Table 41-35.1 Osmolality and Sodium Concentration of Hysteroscopic Distention Media		
Medium	**Osmolality, (mOsm/kg H_2O)**	**Sodium Concentration,(mEq/L)**
Serum	290	135â€"145
Glycine 1.5%	200	â€"
Sorbitol 3% + mannitol 0.5%	178	â€"

Distention medium flow through resectoscope.

Carbon Dioxide

This commonly used distention medium, when used under pressure, tends to flatten the endometrium and gives excellent visibility. A continuous flow is necessary to replace any gas lost through the tubes, and typically flow rates of 40 to 50 mL/min are adequate.

Rates higher than 100 mL/min are associated with increased risks for gas embolism and therefore are discouraged. Specialized hysteroscopic insufflating machines that limit maximum flow rates should be used. Importantly, because laparoscopic insufflating machines can permit flow rates over 1,000 mL/min, these should never be used for hysteroscopy.

Disadvantages to CO_2 include its tendency, when mixed with blood or mucus, to form visually obstructive gas bubbles. Accordingly, prior to hysteroscope insertion, blood and mucus should be carefully removed from the cervical os with a dry swab (Sutton, 2006). Similarly, use of CO_2 with thermal energy sources is avoided because smoke production prohibits adequate visualization. Because of these limitations, CO_2 is best used in patients in whom minimal bleeding is anticipated, such as those needing diagnostic hysteroscopy or requiring simple operative excision (Bieber, 2003).

The most serious complication associated with CO_2 use is venous gas embolism. If vessels are opened during cervical dilation or endometrial disruption, gas under pressure can be forced into the vasculature, and any undissolved portion can reach the lungs. However, because CO_2 is many times more soluble in plasma than room air, it typically dissolves sufficiently during transit from the pelvic region (Corson, 1988). As a result, pulmonary embolism is rare, and severe embolism complicated only 0.03 percent of nearly 4,000 diagnostic CO_2 hysteroscopies in a review of cases by Bradner and colleagues (1999). Avoidance of a steep Trendelenburg position, which lowers the chest to a level below pelvic vessels, is recommended to reduce the risk of pulmonary embolism (Brooks, 1997).

Fluid Media

Bleeding is common with operative hysteroscopy procedures, and fluid media typically are selected in these cases because of their optical clarity and ability to mix with blood.

The main risk of fluid distention media, however, involves increased fluid absorption and fluid volume overload. Volume overload may develop with any of the fluid media and results from a variety of mechanisms. For example, absorption across the endometrium, intravasation through surgically opened venous channels, and spill from the fallopian tubes with absorption by the peritoneum all have been suggested. Accordingly, clinical settings in which procedures are long, increased distention pressure is used, large tissue areas are resected, or a more vascular endothelium is present, all carry a greater risk.

Saline, lactated Ringer's solution, and 5-percent mannitol are isotonic, and volume overload with these may manifest with pulmonary and cerebral edema. Alternatively, hypotonic fluids such as glycine and sorbitol solutions also may intravasate, but large amounts may lead not only to hypervolemia but also to electrolyte dilution, specifically hyponatremia. Mechanistically, glycine and sorbitol are both metabolized following absorption, effectively leaving free water in the intravascular space. Normal serum sodium levels are 135 to 145 mEq/L, and levels below this may lead to seizure followed by respiratory arrest. In addition, hypokalemia and hypocalcemia often can develop concurrently.

Therefore, in patients in whom large fluid volume deficits are reached, measurement of serum electrolyte levels is warranted. If a serum sodium level lower than 125 mEq/L is reached, care should be continued in a critical care setting. Treatment includes stimulation of diuresis with furosemide (Lasix) 20 to 40 mg given intravenously and correction of hyponatremia with 3-percent sodium chloride administered 1 to 1.5 mEq/L per hour. The goal of therapy is to reach a serum sodium level of 135 mEq/L within 24 hours. Overcorrection is avoided to prevent additional cerebral effects (Baggish, 2005).

To assist with fluid volume calculation, most operative hysteroscopes contain continous-flow systems that allow fluid deficits to be calculated. Volume deficits are calculated by the amount of distending media delivered subtracted by the amount returned through collection. Determination of deficits should be performed every 15 minutes during procedures. If a procedure has the potential for larger deficits, a Foley catheter is also warranted for urine output monitoring. The American Association of Gynecologic Laparoscopists recommends that if fluid discrepancy reaches 750 mL, a surgeon should plan for completion of the case. If fluid deficits reach 1,500 mL of a nonelectrolyte solution or 2,500 mL of normal saline, the procedure is concluded immediately, electrolytes measured, and diuretics given as indicated (Loffer, 2000).

Hysteroscopic Electrosurgery

Most hysteroscopic tissue resection or desiccation relies on monopolar current. Because current is dissipated and thus is ineffective in electrolyte solutions, these techniques typically have required nonelectrolyte solutions such as sorbitol, mannitol, and glycine.

However, as discussed earlier, these media can be associated with hyponatremia if fluid volume overload develops. Alternatively, a bipolar electrosurgery system (Versapoint Bipolar Electrosurgery System, Ethicon, Somerville, NJ) allows use of traditional hysteroscopic tools in a saline solution.

SURGICAL COMPLICATIONS

Uterine Perforation

In addition to fluid overload, uterine perforation or bleeding may complicate hysteroscopic procedures. The uterus may be perforated during uterine sounding, cervical dilation, or hysteroscopic procedures (Cooper, 2000). Fundal perforations created by sounds, dilators, or hysteroscopes can be managed conservatively because the myometrium typically will contract around these defects. In contrast, because lateral perforation may injure larger pelvic vessels, posterior perforation may injure the rectum, and perforation caused by electrosurgical tools may cause organ laceration or burn, diagnostic laparoscopy is warranted in these patients. Similarly, anterior perforations should prompt cystoscopy to evaluate associated bladder injury.

Hemorrhage

Heavy bleeding may develop during or following resection procedures. Although hysteroscopic electrosurgical electrodes may be used to contact and coagulate smaller vessels, these may be less effective for larger vessels.

If heavy bleeding is encountered and is refractory to electrosurgical coagulation, termination of the procedure may be indicated. A Foley catheter balloon can be placed into the endometrial cavity and inflated incrementally with 5 to 10 mL of saline until moderate resistance to catheter tension is noted. An attached collection bag can be used to document blood loss and bleeding cessation, at which point the catheter may be removed.

Surgical Steps

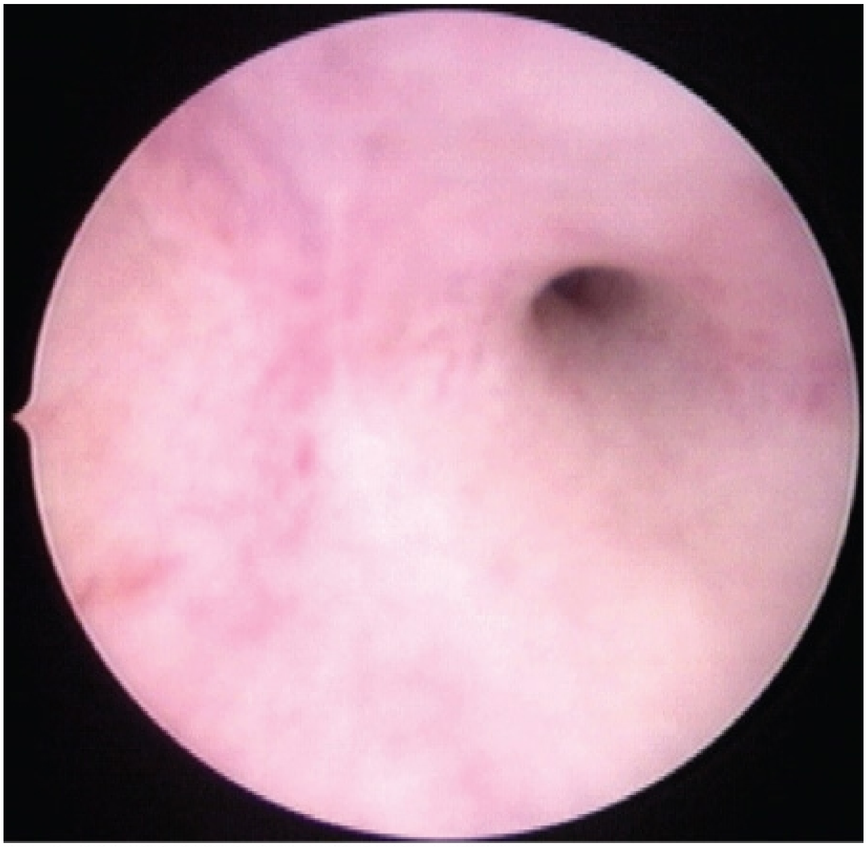
1. **Anesthesia and Patient Positioning.** Diagnostic hysteroscopy can be performed in an outpatient setting under local analgesia with or without intravenous sedation. Alternatively, a day-surgery setting and general anesthesia may be selected.

   The patient is placed in a dorsal lithotomy position, and the vagina is surgically prepared. Because diagnostic hysteroscopy is a short procedure with little, if any, blood loss, CO_2 or a saline typically is selected for uterine distension.

2. **Hysteroscope Introduction.** For most diagnostic hysteroscopic procedures, cervical dilation is not required to admit the 4- to 5-mm hysteroscope. A single-toothed tenaculum is placed on the anterior cervical lip, the flow of distention medium is begun, and the hysteroscope is introduced into the endocervical canal. Pressure exerted by the distention medium opens the endocervical canal and allows hysteroscope entry.

3. **Hysteroscopic Evaluation.** As the hysteroscope is inserted, the endocervical canal is examined for abnormalities. On entering the cavity, the hysteroscope is held at the distal portion of the cavity to allow a panoramic evaluation. Systematically, the hysteroscope is moved to the fundus and then to the left and right to permit inspection of the tubal ostia (Fig. 41-35.4).

FIGURE 41-35.4



Source: Schorge JO, Schaffer JI, Halvorson LM, Hoffman BL, Bradshaw KD, Cunningham FG: *Williams Gynecology*: http://www.accessmedicine.com

Hysteroscopic photograph of normal tubal ostia. (Courtesy of Dr. Kevin Doody.)

4. **Specific Procedures.** After complete inspection, if specific lesions are identified, they typically are biopsied with hysteroscopic forceps.

   If intrauterine device (IUD) removal is planned, most are grasped by the string or stem with hysteroscopic forceps and are extracted easily as the entire hysteroscope is removed (Fig. 41-35.5). However, embedded or fragmented devices may require removal in pieces. In these instances, a sturdy portion of the IUD is grasped firmly, and traction on the forceps is exerted toward the vagina. For patients in whom the IUD is deeply embedded, laparoscopy can assist in identifying uterine perforation and in determining whether the device is best removed hysteroscopically or laparoscopically.

5. **Procedure Completion.** At the end of the procedure, the flow of distending medium is stopped, and hysteroscope and tenaculum are removed.

Postoperative

Patient recovery typically is rapid and without complication and mirrors that following dilatation and curettage. Diet and activities may be resumed as desired by the patient. Spotting or light bleeding is not uncommon and typically stops within days.

41-36 ENDOMETRIAL ABLATION PROCEDURES

Endometrial ablation broadly describes a group of hysteroscopic procedures that destroys or resects the endometrium and for many women, serves as an effective treatment of abnormal uterine bleeding. Within the ablation group, techniques are defined as *first-* or *second-generation* depending on their temporal introduction into use and the need for hysteroscopic skills. First-generation tools require advanced hysteroscopic skills and longer operating times and can be associated with distention media complications. These techniques include endometrial desiccation with the neodymium:yttrium-aluminum-garnet (Nd-YAG) laser, rollerball electrosurgical desiccation, and endometrial resection by resectoscope.

With comparison of first-generation methods, it appears that all three produce similar outcomes in terms of decreased uterine

bleeding and patient satisfaction. However, resection methods have been associated with more surgical complications, and thus desiccation methods within this group may be preferred for women without intracavitary lesions (Lethaby, 2002; Overton, 1997).

To obviate skill requirements and risks of these early ablative tools, second-generation methods have been introduced over the last 10 years. These tools use a variety of modalities to ablate the endometrium, including thermal energy, cryosurgery, electrosurgery, and microwave energy, but without the need for direct hysteroscopic guidance.

Preoperative

PATIENT EVALUATION

Prior to ablation, complete evaluation of abnormal uterine bleeding should be completed. Accordingly, the possibility of pregnancy, endometrial cancer, and active pelvic infection should be excluded. During evaluation of bleeding, transvaginal sonography (TVS), saline-infusion sonography (SIS), and hysteroscopy may be used solely or in combination (see Chap 8, Endometrial Biopsy). However, because many second-generation ablation techniques require a normal endometrial cavity, and because endometrial pathology, if identified, can be treated concurrently by several of the ablative methods, SIS or hysteroscopy is preferred for preoperative evaluation.

CONSENT

Patients selecting ablation should be aware of success rates relative to other treatment options for abnormal bleeding, as discussed in Chapter 8, Endometrial Destructive Procedures. In general, rates of decreased flow range from 70 to 80 percent, and of amenorrhea, from 15 to 35 percent. Therefore, a patient should not undergo ablation if guaranteed amenorrhea is a treatment goal. In addition, endometrial ablation effectively destroys the endometrium and is contraindicated in those who desire future fertility.

Complications associated with ablation mirror those with operative hysteroscopy, although the risk of fluid volume overload is avoided with second-generation tools.

PATIENT PREPARATION

During hysteroscopic surgeries, bacteria in the vagina may gain access to the upper reproductive tract and peritoneal cavity. Although there are no strong evidence-based data to support the use of prophylactic antibiotics, their use seems reasonable with these surgeries. We typically administer cefazolin 2 g intravenously immediately prior to surgery.

Because the endometrium can thicken from only a few millimeters in the early proliferative phase to deeper than 10 mm in the secretory phase, all first-generation techniques and some second-generation techniques should be performed in the early proliferative phase. Otherwise, drugs that induce endometrial atrophy such as gonadotropin-releasing hormone (GnRH) agonists, combination oral contraceptives, or progestins may be used for 1 to 2 months prior to surgery, or curettage may be performed immediately prior to surgery.

Intraoperative

Surgical Steps

1. **Anesthesia and Patient Positioning.** Endometrial ablation typically is a day-surgery procedure performed under general anesthesia. The patient is positioned in the dorsal lithotomy position, and the perineum and vagina are surgically prepped.

2. **Selection of Distending Medium.** With first-generation procedures, distending medium is required and selected based on the destructive energy used (see Section 41-35, Hysteroscopy). In general, saline may be used for laser and bipolar electric current, whereas monopolar tools require nonelectrolyte solutions.

3. **Neodymium:Yttrium-Aluminum-Garnet (Nd:YAG) Laser.** Introduced in the 1980s, the Nd:YAG laser was the first ablative tool. Under direct hysteroscopic observation and uterine distention with saline, an Nd:YAG laser fiber touches the endometrium and is dragged across the endometrial surface to create furrows of photocoagulated tissue 5 to 6 mm in depth (Garry, 1995; Goldrath, 1981).

4. **Trancervical Resection of the Endometrium (TCRE).** In attempts to lower cost from expensive laser equipment, transcervical resection of the endometrium (TCRE) was developed (DeCherney, 1983, 1987). In addition to less expense, because of the larger loop diameter, TCRE can be completed more quickly than ablation with a laser fiber and thereby can reduce the risk of excess medium absorption.

   This procedure uses a resectoscope with monopolar or bipolar electric current to excise strips of endometrium. The resection technique is similar to that described for hysteroscopic myomectomy, as discussed in Section 41-37, Hysteroscopic Myomectomy. Excised tissue strips are sent for pathologic evaluation (Garry, 1995; Lethaby, 2002; Vilos, 2004). Moreover, in patients with concurrent intrauterine pathology such as endometrial polyps or submucous leiomyomas, TCRE can excise these lesions in addition to the endometrium.

   However, TCRE has been associated with higher rates of perforation, especially at the cornual areas, where the myometrium is thinner. For this reason, many use a rollerball electrosurgical electrode in combination with TCRE, with the rollerball used in the cornual region (Oehler, 2003).

5. **Rollerball.** A 2- to 4- mm ball- or barrel-shaped electrosurgical electrode can be rolled across the endometrium as an effective means of vaporizing the endometrium (Vancaillie, 1989). Advantages to rollerball ablation compared with TCRE include shorter operating time, less fluid absorption, and lower rate of perforation. Unfortunately, it is not effective in the treatment of intracavitary lesions, and pathology specimens are not obtained.

6. **Thermal Balloon Ablation.** The first thermal balloon ablation system was used in the early 1990s. Since its introduction, several thermal balloon ablation systems are currently used worldwide (Fig. 41-36.1). The ThermaChoice III Uterine Balloon Therapy System (Gynecare, Division of Ethicon, Somerville, NJ) is approved for use in the United States, but not the Cavaterm Plus System (Wallsten Medical SA, Morges, Switzerland) or the Thermablate Endometrial Ablation System (MDMI Technologies, Richmond, BC, Canada).

   The ThermaChoice III Uterine Balloon Therapy System is a software-controlled device designed to ablate endometrial tissue using thermal energy. A 5-percent dextrose and water solution is instilled into a disposable silicone balloon and heated to coagulate the endometrium. During treatment, the fluid within the balloon is circulated to maintain a temperature of 87Â°C (186Â°F) for 8 minutes. The balloon can be introduced without hysteroscopic assistance into the uterine cavity and when inflated, conforms to the cavity contour.

   All hot-liquid balloon devices require no advanced hysteroscopic skills, and complication rates are low (Gurtcheff, 2003; Vilos, 2004). Disadvantages include the requirement of an anatomically normal uterine cavity and of pharmacologic thinning prior to thermal ablation. Alternatively, mechanical thinning can be accomplished with dilatation and curettage prior to ablation.

Source: Schorge JO, Schaffer JI, Halvorson LM, Hoffman BL, Bradshaw KD, Cunningham FG: *Williams Gynecology*: http://www.accessmedicine.com

ThermaChoice III Uterine Balloon Therapy System. (Courtesy of Gynecare.)

7. **Hysteroscopic Thermal Ablation.** Several second-generation ablation procedures require a normal uterine cavity. However, the HydroThermAblator (HTA) (Boston Scientific, Natick, MA) system allows treatment of the endometrium concurrent with submucous leiomyomas, polyps, or abnormal uterine contour.

   This tool is designed to ablate the endometrial lining of the uterus by heating an uncontained saline solution to a temperature of 90Â°C and recirculating it through the uterus for 10 minutes (Fig. 41-36.2). Spill through the fallopian tubes is avoided because hydrostatic pressure during the procedure remains below 55 mm Hg, which is well below pressures needed to open the tubes. Similarly, the water seal created between the hysteroscope and the internal cervical os prevents leakage of fluid into the vagina. For this reason, care should be taken not to dilate the cervix to a diameter greater than 8 mm. Additionally, preoperative laminaria are not recommended.

   Initially, a hysteroscope is inserted into the 7.8-mm-diameter disposable HTA sheath. This combination is introduced into the endometrial cavity to enable visualization while room-temperature saline is instilled into the uterine cavity. The fluid then is heated gradually and circulated to treat the endometrium. At completion of the treatment phase, cool saline solution replaces the heated fluid, and the instrument then is removed (Glasser, 2003).

FIGURE 41-36.2

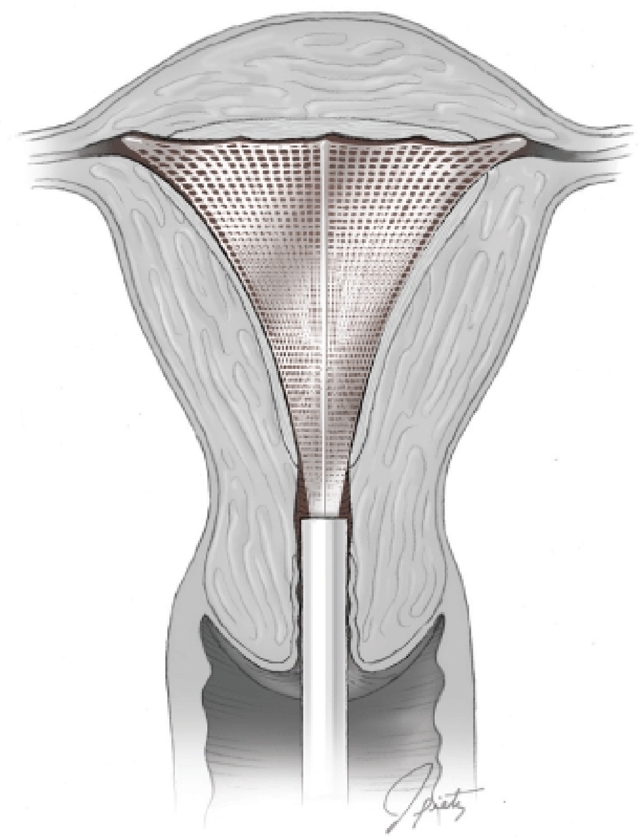
Hysteroscopic thermal ablation.

8. **Impedance-Controlled Electrocoagulation.** The NovaSure Endometrial Ablation System (Cytyc Corp, Marlborough, MA) was approved for marketing in the United States in 2001. The system consists of a high-frequency (radiofrequency) electrosurgical generator and a single-use three-dimensional, metal, fabric-like mesh that is designed to contour to the shape of the endometrial cavity. During treatment, an attachment provides suction to firmly draw the endometrium and myometrium up against the mesh electrode for improved contact and to remove generated vapor (Fig. 41-36.3).

FIGURE 41-36.3



Source: Schorge JO, Schaffer JI, Halvorson LM, Hoffman BL, Bradshaw KD, Cunningham FG: *Williams Gynecology*: http://www.accessmedicine.com

Impedance-controlled electrocoagulation.

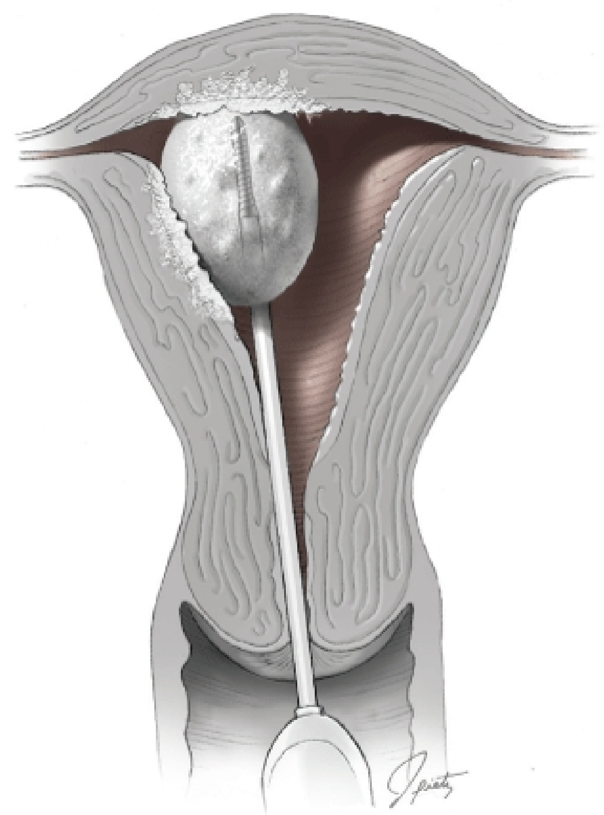
9. **Microwave Ablation (MEA).** Approved in 2003 for use in the United States, the Microwave Endometrial Ablation (MEA) Technique (Microsulis Plc, Waterlooville, Hampshire, UK) uses microware energy to destroy the endometrium. During the procedure, a microwave probe is inserted until the tip reaches the uterine fundus. Once inserted, the probe tip is maintained at 75 to 80Â°C and moved slowly from side to side. Microwave energy is spread with a maximum penetration of 6 mm over the entire surface of the uterine cavity. Speed is an advantage, with the entire treatment completed in 2 to 3 minutes (Cooper, 1999).

10. **Cryoablation.** In addition to thermal damage, endometrial ablation can be achieved with extreme cold. The Her Option (American Medical Systems, Minnetonka, MN) Cryoablation System was approved for use in the United States in 2001. Similar to the physics of cervical cryotherapy, gases compressed under pressure with this unit can generate temperatures of â€"100 to â€"120Â°C at the cryoprobe tip to produce an iceball. As the iceball grows, its leading edge advances through tissue, and cryonecrosis develops in those tissues, reaching temperatures less than â€"20Â°C (see Section 41-13, Treatment of Ectocervical Preinvasive Lesions).

    The Her Option Cryoablation System contains a metal probe that is covered by a 5.5-mm disposable cryoprobe. After dilation of the cervix, the cryoprobe's 1.4-inch cryotip is placed against one side of the endometrial cavity and advanced to the uterine cornua (Fig. 41-36.4). Concurrent transabdominal sonography is required to ensure accurate cryotip placement and surveillance of the increasing iceball diameter, which is seen sonographically as an enlarging hypoechoic area (American

Medical Systems, 2006). The first freeze is terminated after 4 minutes or sooner if the advancing iceball reaches to within 3 mm of the uterine serosa. The cryotip is allowed to warm, is removed from the cornua, and is redirected into the contralateral cornua. A second freeze is performed for 6 minutes.

FIGURE 41-36.4



Source: Schorge JO, Schaffer JI, Halvorson LM, Hoffman BL, Bradshaw KD, Cunningham FG: *Williams Gynecology*: http://www.accessmedicine.com

Cryoablation.

Postoperative

Advantages to endometrial ablation include rapid patient recovery and low incidence of complications. Patients may resume normal diet and activities as tolerated. Patients may expect light bleeding or spotting during the first postoperative days as necrotic endometrial tissue is shed. A serosanguineous discharge follows for 1 week and is replaced by a profuse and watery discharge for another 1 to 2 weeks.

As mentioned earlier, ablation has been associated with subsequent pregnancy complications, such as placenta accreta, preterm labor, and spontaneous abortion (Cook, 2003; Hare, 2005). Thus, in women with reproductive function, a reliable contraceptive method must be used following surgery. In many instances, a sterilization procedure may be performed concurrently with ablation.

41-37 HYSTEROSCOPIC MYOMECTOMY

For symptomatic women with submucous leiomyomas, hysteroscopic resection of these tumors may provide relief of symptoms in most cases. Candidates may include those with abnormal uterine bleeding or those with infertility in whom leiomyomas are

suspected to be contributory. Those tumors selected for resection should be either submucous or intramural with a prominent submucous component. During surgery, pedunculated submucous leiomyomas may be excised similarly to polyps, as described in Section 41-41, Lysis of Intrauterine Adhesions. However, those with an intramural component require resection with a resectoscope, morcellator, or laser.

Preoperative

PATIENT EVALUATION

Hysteroscopic myomectomy is a safe and effective option for most women. Contraindications to surgery, however, include pregnancy, potential endometrial cancer, current reproductive tract infection, and medical conditions sensitive to fluid volume overload.

Specific leiomyoma characteristics such as increasing size, number, and degree of intramural penetration can raise the technical difficulty, complication rate, and clinical failure rate of this procedure. Thus, prior to resection, women should undergo saline-infusion sonography (SIS) or hysteroscopy to evaluate leiomyoma characteristics. Alternatively, magnetic resonance (MR) imaging also can accurately document uterine anatomy, but its expense and availability may limit its routine use.

During SIS evaluation, leiomyomas may be grouped according to criteria from the European Society of Hysteroscopy:

- Class 0: Complete submucosal location
- Class I: Greater than 50 percent submucosal component
- Class II: Some submucosal involvement but greater than 50 percent myometrial component

Large or predominantly intramural tumors decrease clinical success rates and increase surgical risks and the need for more than one surgical session to complete resection. For these reasons, many choose to resect only type 0 and type I tumors and those measuring less than 3 cm (Vercellini, 1999; Wamsteker, 1993).

CONSENT

In general, complications of this procedure mirror those for hysteroscopy, and rates of 2 to 3 percent have been reported (see Section 41-35, Hysteroscopy). However, hysteroscopic myomectomy is associated with a greater risk of uterine perforation. This complication may follow cervical dilatation but more frequently results during aggressive resection into the myometrium. Because of this risk, women also should be consented for diagnostic laparoscopy.

Additionally, patients planning to seek pregnancy should be aware of possible intrauterine adhesion formation following resection and of rare uterine rupture during subsequent pregnancies (Batra, 2004; Howe, 1993).

Women with type I or type II tumors or those with large leiomyomas should be counseled that a second surgery may be required to finish resections that may have been halted due to advancing fluid volume deficits. Fortunately, because of newer hysteroscopic morcellating tools, operating times and thus fluid deficits are decreased, even with large tumors. Additionally, although myomectomy is an effective treatment, 15 to 20 percent of patients eventually will require reoperation, either hysterectomy or repeat hysteroscopic resection, at a later time for either persistent or recurrent symptoms (Derman, 1991; Hart, 1999).

PATIENT PREPARATION

As discussed in Chapter 9, GnRH Agonists, gonadotropin-releasing hormone (GnRH) agonists can shrink leiomyomas preoperatively to enable resection of large tumors or allow patients to rebuild their red cell mass before surgery. Advantages and disadvantages of these drugs warrant individualization of their use (Table 41-37.1).

Table 41-37.1 Factors that Affect the Decision to Use Gonadotropin-Releasing Hormone Agonists Prior to Hysteroscopic Myomectomy		
Parameter	**Disfavoring Pretreatment**	**In Favor of Pretreatment**
Anemia	None or mild	Pronounced
Type of myoma	Types 0 and I	Type II
Diameter	<2 cm	>3 cm
Residual distance to the serosa	>10 mm	<8 mm
Number of leiomyomas	Single	Multiple
Leiomyoma location	Anterior, posterior, and lateral wall	Fundus, close to tubal ostium
Ability of the surgeon	Highly skilled	Less skilled

Adapted from Brandner, 2000, with permission.

To allow easier cervical dilatation and resectoscope insertion, laminaria tents may be place the evening prior to surgery. Alternatively, misoprostol also has ben shown to aid dilatation in some but not all studies, and postmenopausal women may benefit less from this pretreatment (Ngai, 2001; Preutthipan, 2000). We typically prescribe misoprostol 100 µg orally the evening prior to and the morning of surgery.

Although the risk of postoperative infection is low, because pelvic infections can have devastating effect on future fertility, most surgeons recommend antibiotic prophylaxis prior to extensive hysteroscopic resections, as with myomectomy.

CONCURRENT ABLATION

In women with menorrhagia and with no desire for future fertility, endometrial ablation may be performed concurrently (see Section 41-36, Endometrial Ablation Procedures) (Loffer, 2003). However, because leiomyoma resection alone will correct abnormal bleeding in most women, we do not perform adjunctive endometrial ablation routinely unless the patient desires hypomenorrhea.

Intraoperative

INSTRUMENTS

Hysteroscopic myomectomy can be performed using a resectoscope or hysteroscopic morcellator. Both procedures will be described.

Surgical Steps

1. **Anesthesia and Patient Positioning.** For most patients, hysteroscopic myomectomy is an outpatient procedure performed under general anesthesia. The patient is placed in dorsal lithotomy position, the vagina is surgically prepared, and a Foley catheter is placed.

2. **Medium Selection.** The choice of distending medium is dictated by the resecting tool used. Resection using a morcellator, bipolar electrosurgical loop, or laser can be performed in saline solution. Alternatively, cases using a monopolar electrosurgical loop require an electrolyte-free solution (see Section 41-35, Hysteroscopy).

3. **Cervical Dilatation.** Using Pratt or other suitable dilators, the surgeon dilates the cervix as described in Section 41-16, Sharp Dilatation and Curettage.

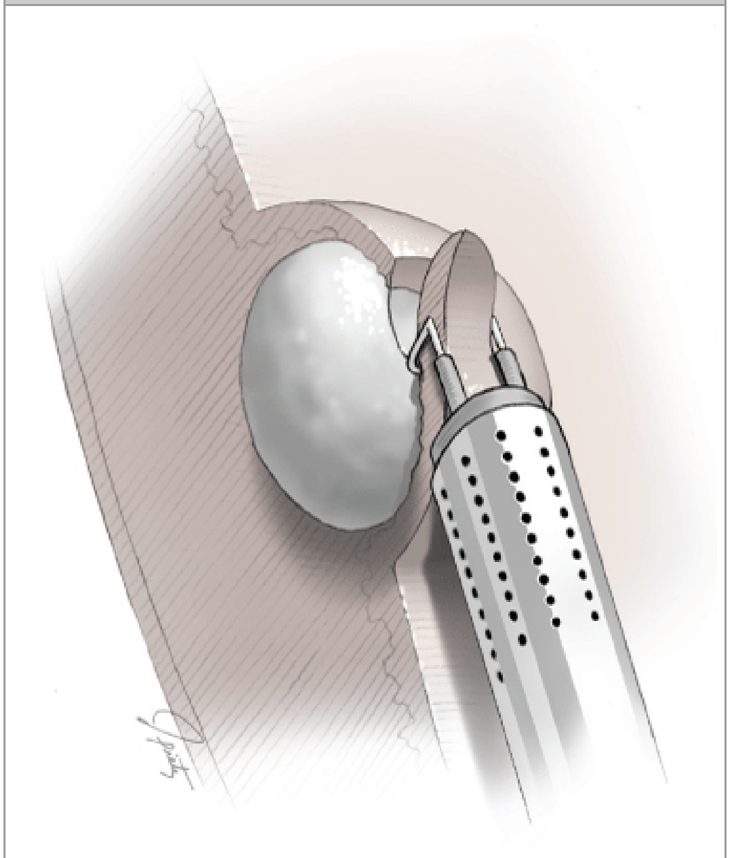
4. **Instrument Insertion.** The distending medium flow is begun, and the resectoscope or morcellator is inserted into the endocervical canal under direct visualization. On entering the endometrial cavity, a panoramic inspection is performed first to

identify leiomyomas.

5. **Resection.** The electrosurgical unit is set to a continuous-wave mode (cutting). The resectoscope loop is advanced to lie behind the leiomyoma, and electric current is applied before the loop contacts the tissue. To minimize thermal injury and perforation, current should be applied only as the loop is retracted and not when it is being extended. On contact, the loop electrode is retracted toward the resectoscope (Fig 41-37.1). To ensure a clean cut and complete excision of the shaved strip, current is not stopped until the entire loop is retracted. The shaved strip of smooth muscle floats within the endometrial cavity.

   This shaving process is repeated serially toward the leiomyoma's base until the tumor is removed. Although strips can be removed from the cavity after each pass, this results in a repetitive loss of uterine distention. Repeated removal and reinsertion of a resectoscope increase the risk of perforation and fluid intravasation. Thus, in most cases, pushing removed strips to the fundus will help to clear the operative field adequately. However, if the view becomes obstructed, a pause in resection may be required to remove these strips.

FIGURE 41-37.1



Source: Schorge JO, Schaffer JI, Halvorson LM, Hoffman BL, Bradshaw KD, Cunningham FG: *Williams Gynecology*: http://www.accessmedicine.com

Hysteroscopic resection.

6. **Morcellation.** The Intra Uterine Morcellator (IUM, Smith & Nephew Endoscopy, Andover, MA) consists of two hollow, rigid, disposable tubes that fit within one another (Fig. 41-37.2). The inner tube rotates within the outer and is driven mechanically by an electrically powered control unit. The IUM for leiomyomas has a reciprocating cutting action with an optimal

performance at 1,100 rotations per minute (rpm). By means of a vacuum source connected to the inner tube, tissue is suctioned into the window opening at the tip of the device and is shaved off as the inner tube rotates. Suction also removes morcellated tissue through the device and allows collection in a net bag for pathologic analysis. When rotation of the inner tube is not activated, the morcellator window opening is always closed to prevent suction of distention fluid, uterine cavity collapse, and risk of perforation. In retrospective comparisons, hysteroscopic morcellation is faster than resectoscopy and appears easier to perform. It is associated with fewer fluid-related complications and a shorter learning curve than conventional resectoscopy (Emanuel, 2005).

C

Hysteroscopic morcellator. **A.** Morcellator blade retracted. Suction draws tissue into the fluted opening. **B.** Blade partially advanced. The blade rapidly rotates as it is advanced and retracted **C.** Blade is fully advanced and slices tissue drawn into the opening.

7. **Intramural Leiomyomas.** During removal of leiomyomas with an intramural component, uterine perforation risks are increased if resection extends below the level of the normal myometrium. Therefore, when resection reaches this level, the surgeon should pause and wait for the surrounding myometrium to contract around the now smaller tumor and deliver deeper portions of the leiomyoma into the uterine cavity (see Fig. 41-37.1).

8. **Fluid Volume Deficit.** Because of the risk of hypervolemia during hysteroscopic myomectomy, fluid volume deficit should be monitored carefully, as discussed in Section 41-35, Hysteroscopy.

9. **Hemostasis.** Bleeding is common during myomectomy, and vessels may be coagulated with the edge of the resecting loop with the electrosurgical unit set to a coagulating current. At times, a ball electrode may be required to increase the surface area over which current is delivered. Rarely, hemorrhage may not be controlled with electrosurgical means. In these cases, mechanical pressure applied to bleeding vessels by a Foley balloon inflated with 5 to 10 mL of saline may be required.

Postoperative

Recovery following myomectomy is quick and typically without complication. Patients may resume diet and activities as tolerated. Spotting or light bleeding may follow surgery for 1 to 2 weeks.

For patients desiring pregnancy, conception may be attempted in the menstrual cycle after the resection unless the leiomyoma was broad based or had a significant intramural component. In these patients, barrier contraception is advised for three cycles. For women who fail to conceive or continue to have abnormal bleeding following resection, postoperative hysterosalpingography or hysteroscopy is recommended.

41-38 POLYPECTOMY

Indications for the removal of endometrial polyps include abnormal uterine bleeding, infertility, and risk of malignant transformation (see Chap. 8, Endometrial Polyp). Hysteroscopic excision of these growths may be completed by incision of the polyp base with hysteroscopic scissors or resectoscope loop, avulsion of the polyp with hysteroscopic forceps, or morcellation. Of these, the resectoscope and morcellator offer the most versatility in managing lesions, both large and small.

Preoperative

PATIENT EVALUATION

In many women undergoing polypectomy, preoperative transvaginal sonography or saline-infusion sonography have been completed, and information regarding the size, number, and location of polyps should be reviewed prior to surgery (see Figs. 8-7

and 8-8).

CONSENT

The complication rates for this procedure are low and mirror those for hysteroscopy in general (see Section 41-35, Hysteroscopy) (Jansen, 2000).

PATIENT PREPARATION

As with most hysteroscopic procedures, polypectomy ideally is performed during the follicular phase of the menstrual cycle when the endometrial lining is thinnest and polyps would be most easily identified. The need for antibiotic prophylaxis is unclear and may be left to surgeon discretion.

Intraoperative

INSTRUMENTS

As described earlier, a resectoscope with a 90-degree loop electrode is ideal for polyp excision. Alternatively, an intrauterine morcellator also can quickly excise even large growths.

Surgical Steps

1. **Anesthesia and Patient Positioning.** Although simple polypectomy procedures, under local analgesia in an office setting, have been described, most are outpatient procedures performed under general anesthesia. Following administration of adequate anesthesia, the patient is placed in dorsal lithotomy position, the vagina is surgically prepared, and a Foley catheter is placed.

2. **Media Selection.** Hysteroscopic morcellation is performed with a physiologic saline solution. If a monopolar resectoscope is used, then a nonelectrolyte solution is required (see Section 41-35, Hysteroscopy). Alternatively, selection of a bipolar resecting system (Versapoint, Ethicon, Somerville, NJ) allows performance within saline. As with any hysteroscopic procedure, fluid volume deficits are calculated and noted every 15 minutes during surgery.

3. **Cervical Dilatation.** The larger diameter of an 8- or 10-mm resectoscope or morcellator typically requires dilatation up to 9 mm with Pratt or other similar dilators.

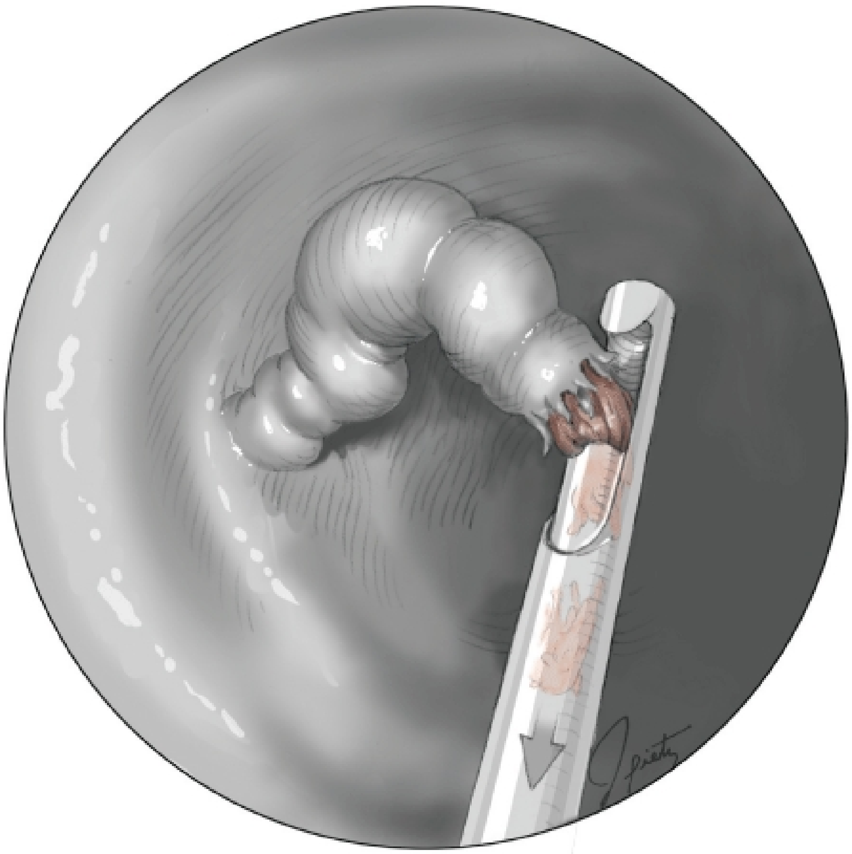
4. **Resection.** Medium flow is begun, and the resectoscope is inserted into the endocervical canal under hysteroscopic visualization. On entering the cavity, a panoramic inspection is completed to identify the location and number of polyps. The resectoscope loop then is extended to reach behind the polyp. Electrosurgical current is applied as the loop is retracted toward the cervix to cut the polyp base. The freed polyp then is grasped and delivered through the cervical os.

   In patients in whom the polyp is large, several passes with the loop electrode may be required for complete excision. Passes begin at the polyp tip and progress until the base is reached.

5. **Morcellation.** As with loop resection, saline solution flow is begun, and the morcellation unit is inserted. During morcellation, it is important to work from the polyp periphery toward the base (Fig. 41-38.1). Moreover, the tumor should be kept between the morcellator opening and the optics of the camera.

   The morcellator has suction action as well. This can be used apart from its cutting effects to clear blood, tissue dÃ©bris, and clots during resection of large growths.

FIGURE 41-38.1



Source: Schorge JO, Schaffer JI, Halvorson LM, Hoffman BL, Bradshaw KD, Cunningham FG: *Williams Gynecology*: http://www.accessmedicine.com

Hysteroscopic polypectomy.

6. **Control of Bleeding.** Bleeding sites may be coagulated with the same resection loop using a coagulating current. For heavy bleeding, a Foley catheter balloon may be inflated as described in Surgical Steps.

7. **Instrument Removal.** The resectoscope or morcellator is removed, and the surgical specimen is sent for pathologic evaluation.

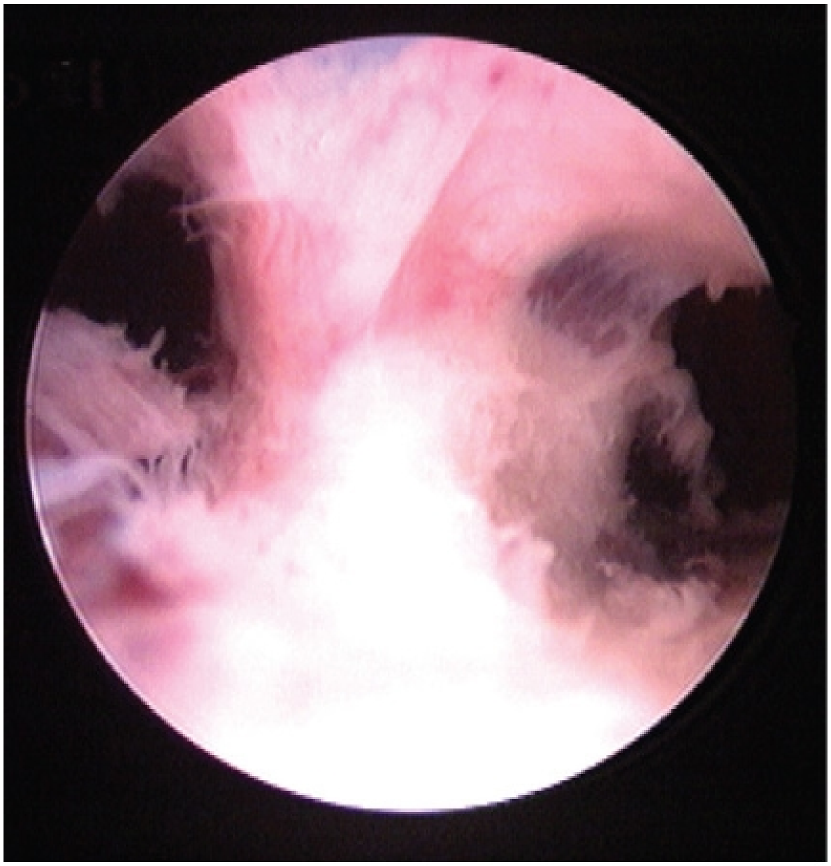
Postoperative

Recovery following polypectomy is rapid, is typically without complication, and follows that for other hysteroscopic procedures (see Section 41-35, Hysteroscopy).

41-39 SEPTOPLASTY

A uterine septum typically results from incomplete medial regression of the mÃ¼llerian ducts during their fusion (Fig. 41-39.1; see also Chap 18, Gonadal Differentiation). These septa have been associated with increase rates of first- and second-trimester spontaneous abortion, and this serves as the main indication for septum excision. Before the popularity of operative hysteroscopy, septoplasty was performed abdominally and with a hysterotomy incision. Fortunately, hysteroscopic septoplasty affords decreased morbidity to the patient and uterus and currently is preferred.

FIGURE 41-39.1



Source: Schorge JO, Schaffer JI, Halvorson LM, Hoffman BL, Bradshaw KD, Cunningham FG: *Williams Gynecology*: http://www.accessmedicine.com

Hysteroscopic photograph of uterine septum. (Courtesy of Dr. Kevin Doody.)

Preoperative

PATIENT EVALUATION

Diagnosis of the septate uterus is outlined in Chapter 18, Diagnosis and Treatment, and includes hysterosalpingography (HSG) and sonography. Because of the frequent association between renal and mÃ¼llerian anomalies, intravenous pyelography is also performed. Finally, although a septate uterus is associated with infertility and pregnancy loss, evaluation for other causes of these two conditions should be completed prior to septum excision. Contraindications to septoplasty include pregnancy and active pelvic infection, and these should be excluded.

CONSENT

Hysteroscopic septoplasty is a safe and effective method of treatment for pregnancy loss, and postoperative live birth rates approximate 85 percent (Fayez, 1986).

In general, complications mirror those for operative hysteroscopy, although the risk of uterine perforation appears increased. For this reason, concurrent laparoscopy is recommended with this procedure to help inform a surgeon as to the proximity of the uterine serosa. As the hysteroscope nears the fundal serosa, transillumination via the hysteroscope light indicates the potential for uterine perforation. Accordingly, a patient should be consented for concurrent diagnostic laparoscopy, as outlined in Section 41-28, Laparoscopy.

PATIENT PREPARATION

As with most operative hysteroscopic procedures, antibiotic prophylaxis is warranted. A first- or second-generation cephalosporin or other suitable antibiotic is appropriate. Additionally, laminaria tents or misoprostol may be used preoperatively to ease cervical dilatation (see Section 41-35, Hysteroscopy).

Intraoperative

INSTRUMENTS

Septum resection may be completed using hysteroscopic scissors, resectoscope loop, or neodymium:yttrium-aluminum-garnet (Nd:YAG) laser. Selection is based on surgeon preference and skill.

Surgical Steps

1. **Anesthesia and Patient Positioning.** Hysteroscopic septoplasty typically is a day-surgery procedure performed under general anesthesia. Because concurrent laparoscopy is recommended, a woman is placed in the dorsal lithotomy position, the abdomen and vagina are surgically prepared, and a Foley catheter is inserted.

2. **Medium Selection.** The choice of distending medium is dictated by the incising tool used. Sharp incision with scissors, Nd:YAG laser, or bipolar instrument is commonly selected and can be performed in any liquid medium (see Section 41-35, Hysteroscopy).

3. **Concurrent Laparoscopy.** Because of the increased risk of uterine perforation, adjunctive laparoscopy is warranted. Placement of the laparoscope follows the steps described in Section 41-28, Laparoscopy.

4. **Cervical Dilatation.** A tenaculum is placed on the anterior cervical lip. Using a Pratt or other suitable dilator, the surgeon dilates the cervix as described in Section 41-16, Sharp Dilatation and Curettage.

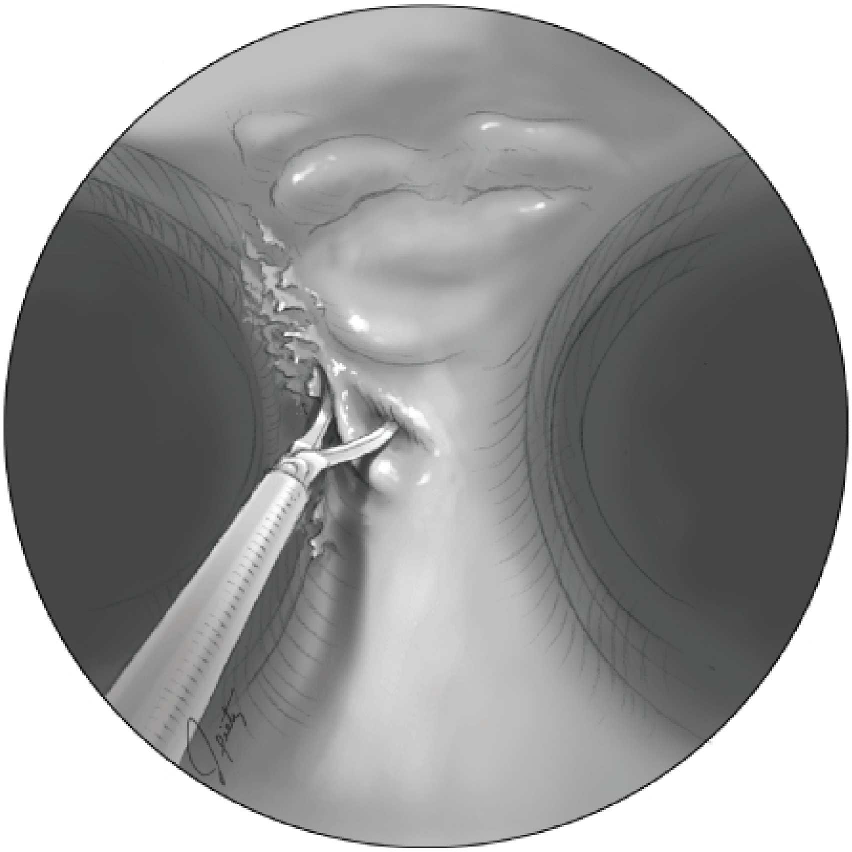
5. **Instrument Insertion.** The distending medium flow is begun, and the operative hysteroscope is inserted into the endocervical canal under direct visualization. On entering the endometrial cavity, a panoramic inspection is performed first to identify the septum.

6. **Septum Incision.** When scissors are used, a surgeon should attempt to keep the line of the incision in the anteroposterior midline. Transection begins caudally, at the septum apex, and continues cephalad toward the fundus. Bites with the scissors are taken bilaterally and are directed toward the horizontal midline (Fig. 41-39.2). During incision of the septum, drifting from the vertical midline is common. Incisions typically drift posteriorly in an anteverted uterus and anteriorly in a retroverted one. Thus, the surgeon may pause and re-orient periodically.

   During septoplasty, incision rather than complete resection of the septum is sufficient. Septal stumps are retracted into the myometrium as the septum is transected.

   In most cases, the septum is relatively avascular, and cutting at its midpoint typically causes little bleeding. As a result, clues that indicate that transection is complete include reaching tissue of increasing vascularity, receiving instruction from the laparoscopist that the hysteroscope is nearing the uterine serosa, and reaching a level in line with the tubal ostia.

FIGURE 41-39.2



Source: Schorge JO, Schaffer JI, Halvorson LM, Hoffman BL, Bradshaw KD, Cunningham FG: *Williams Gynecology*: http://www.accessmedicine.com

Septum incision.

7. **Procedure Completion.** After incision, the hysteroscope and tenaculum are removed. Completion of laparoscopy follows the steps outlined in Section 41-28, Laparoscopy.

Postoperative

Recovery following septoplasty is rapid and typically without complication. Light bleeding or spotting may last 1 week or more. Patients may resume normal diet and activities as desired.

To stimulate endometrial proliferation and prevent adhesion reformation, oral estrogen administration has proved effective. Although several regimens can be used, we prescribe 2 mg estradiol orally for 30 days.

Attempts at conception should be delayed for 2 to 3 months following surgery. If septum resection appeared incomplete at the time of surgery, or if recurrent miscarriage or amenorrhea develops, then postoperative HSG or a second hysteroscopy should be performed. Complete removal of the septum or adhesiolysis may be required (see Section 41-41, Lysis of Intrauterine Adhesions).

With subsequent pregnancy, if the myometrium was not entered, cesarean delivery is required only for obstetric indications.

41-40 HYSTEROSCOPIC PROXIMAL FALLOPIAN TUBE CANNULATION

Proximal fallopian obstruction may result from pelvic inflammatory disease (PID), intratubal dÃ©bris, congenital malformations,

tubal spasm, endometriosis, tubal polyps, and salpingitis isthmica nodosa (SIN). Therapeutic approaches to occlusion in this portion of the tube include tubal cannulation, surgical tubocornual anastomosis, and in vitro fertilization (IVF) (Kodaman, 2004).

Proximal fallopian tube cannulation may be performed as an outpatient radiologic procedure using fluoroscopy (Papaioannou, 2003). Alternatively, cannula placement may be completed with hysteroscopic guidance (Confino, 2003). If a hysteroscopic approach is selected, laparoscopy typically is used concurrently. This allows evaluation and treatment of both proximal and distal tubal disease.

During cannulation, attempts are made to flush out dÃ©bris from within the tubes and perform chromotubation.

Preoperative

PATIENT EVALUATION

Proximal tubal occlusion typically is identified with hysterosalpingography (HSG) during evaluation of female infertility, and this modality is described in Chapters 2, Hysterosalpingography and 19, Hysterosalpingography.

To avoid disruption of an early pregnancy, preoperative beta human chorionic gonadotropin β-hCG testing is warranted in most patients. Although this procedure may be performed at any time during the menstrual cycle, the early proliferative phase offers the advantage of a thinner endometrium to allow easy identification of tubal ostia.

CONSENT

In addition to general complications associated with hysteroscopy and laparoscopy, patients undergoing proximal tubal cannulation should be informed of the small risk of tubal perforation. Fortunately, because the guidewire measures only 0.5 mm in diameter, tubal damage is rarely significant and can be assessed by concurrent laparoscopic examination of the perforated tube.

In most cases, women with both proximal and distal tubal disease are best managed with IVF. As discussed in Chapter 9, Hydrosalpinx, hydrosalpinges, when present, can lower IVF success rates. Thus, consideration of and consent for salpingectomy should accompany plans for proximal tubal cannulation.

PATIENT PREPARATION

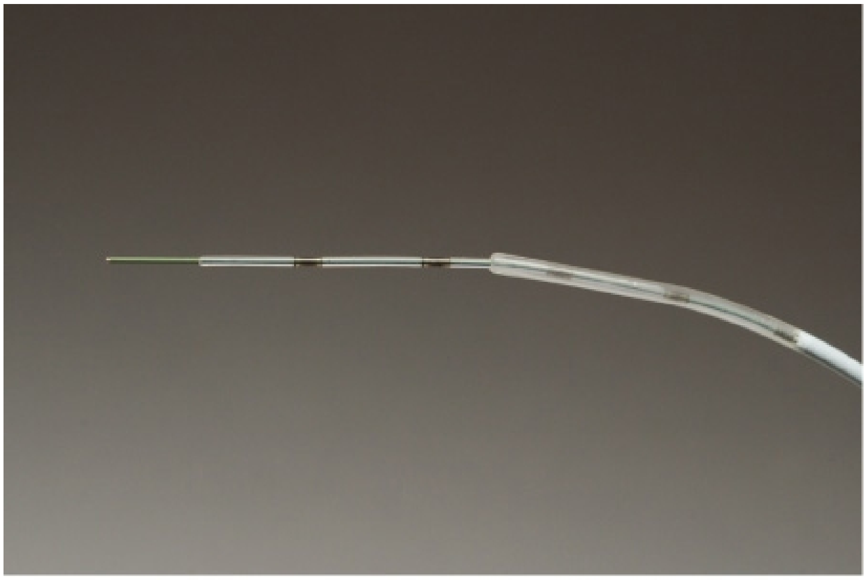
The risk of pelvic infection is low. However, because adhesions following such infection can have damaging effects on fallopian tube health, patients should receive either a first- or second-generation cephalosporin prior to surgery. In addition, laminaria tents or misoprostol may be used to aid in hysteroscope insertion (see Section 41-35, Hysteroscopy).

Intraoperative

INSTRUMENTS

Fallopian tubes may be cannulated with a catheter system such as the one displayed in Figure 41-40.1. This system contains an outer cannula, an inner cannula, and an inner guidewire. The preset bend of the outer cannula aids placement of both the inner cannula and guidewire into the tubal ostium. Once the inner cannula has been threaded into the proximal fallopian tube, the guidewire is removed. The inner cannula, now emptied of the guidewire, can be use to flush dÃ©bris from the fallopian tube and allow chromotubation (see Chap. 19, Laparoscopy).

FIGURE 41-40.1



Source: Schorge JO, Schaffer JI, Halvorson LM, Hoffman BL, Bradshaw KD, Cunningham FG: *Williams Gynecology*: http://www.accessmedicine.com

Photograph of hysteroscopic tubal cannulation catheter.

Surgical Steps

1. **Anesthesia and Patient Positioning.** Hysteroscopic tubal cannulation with concurrent laparoscopy typically is an outpatient procedure performed under general anesthesia. The patient is placed in dorsal lithotomy position, the abdomen and vagina are surgically prepared, and a Foley catheter is placed.

2. **Medium Selection.** No electrosurgery is required for tubal cannulation; thus saline is the preferred medium (see Section 41-35, Hysteroscopy).

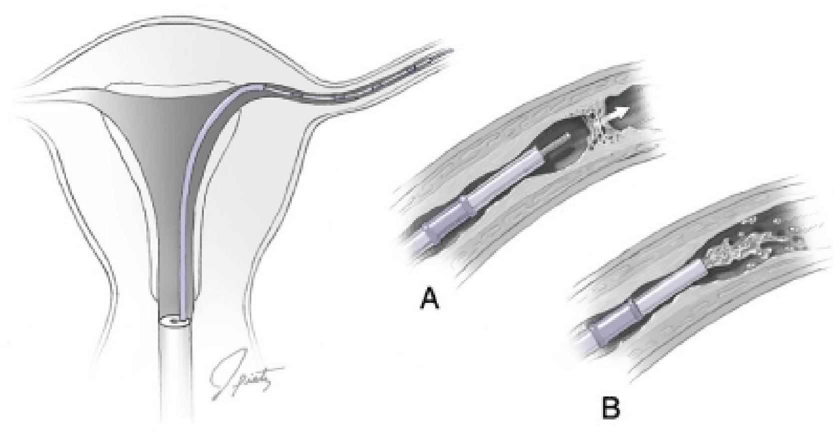
3. **Laparoscopy.** The laparoscope is inserted as described in Section 41-28, Laparoscopy.

4. **Cervical Dilatation.** Because a smaller-diameter operative hysteroscope is required for tubal cannulation, cervical dilatation may not be required. If needed, it is performed as described in Section 41-16, Sharp Dilatation and Curettage.

5. **Hysteroscope Insertion.** The flow of saline is begun, and the hysteroscope is inserted. A panoramic inspection of the entire cavity is performed.

6. **Tubal Cannulation.** The catheter system is threaded through an operating port of the hysteroscope. Under direct visual guidance, the outer catheter is advanced and placed at one of the tubal ostia. The inner catheter then is threaded approximately 2 cm into the proximal fallopian tube (Fig. 41-40.2). The guidewire is removed.

FIGURE 41-40.2



Source: Schorge JO, Schaffer JI, Halvorson LM, Hoffman BL, Bradshaw KD, Cunningham FG: *Williams Gynecology*: http://www.accessmedicine.com

Tubal cannulation.

7. **Tubal Flushing.** The inner catheter is flushed with water-soluble dye. The laparoscope should be positioned to allow inspection of the distal tube to note the presence or absence of dye spill.

8. **Concurrent Procedures.** If distal tubal adhesions are noted, laparoscopic lysis of adhesions may be performed concurrently.

9. **Procedure Completion.** Following cannulation, the hysteroscope and cervical tenaculum are removed. Laparoscopy is completed as described in Section 41-28, Laparoscopy.

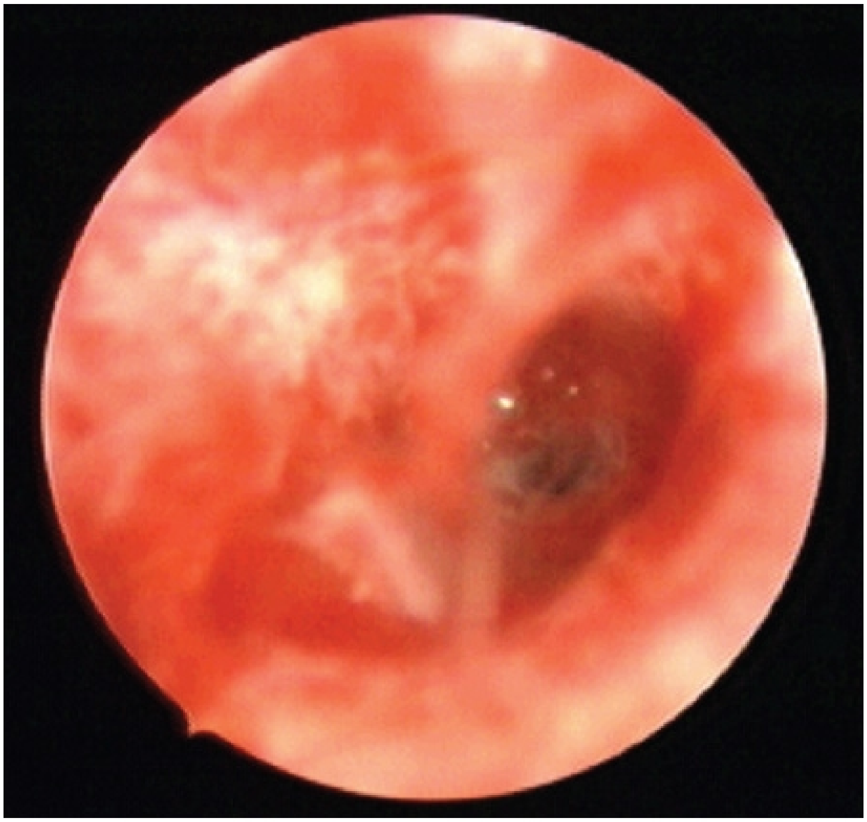
Postoperative

Recovery from hysteroscopic tubal cannulation and laparoscopy typically is quick and uncomplicated. Patients may resume diet, activity, and attempts at conception as desired.

41-41 LYSIS OF INTRAUTERINE ADHESIONS

Intrauterine adhesions, also called *synechiae,* may develop following uterine curettage. Less commonly, they may result from pelvic irradiation or tuberculous endometritis. The presence of these adhesions, also termed Asherman syndrome, may lead to hypo- or amenorrhea and infertility or pregnancy loss in women (Fig. 41-41.1).

FIGURE 41-41.1



Source: Schorge JO, Schaffer JI, Halvorson LM, Hoffman BL, Bradshaw KD, Cunningham FG: *Williams Gynecology*: http://www.accessmedicine.com

Hysteroscopic photograph of intrauterine adhesions. (Courtesy of Dr. Kevin Doody.)

Treatment goals include surgical recreation of normal intrauterine anatomy and prevention of adhesion re-formation. Surgery involves hysteroscopic transection rather than excision of adhesions. Thus, thin adhesions usually can be lysed using only blunt force from the hysteroscopic sheath. Dense adhesions, however, usually require hysteroscopic division with scissors or laser tip.

Postoperative pregnancy and live delivery rates are markers of surgical success. These rates vary depending on the thickness of adhesions and the degree of cavity obliteration. For this reason, various adhesion classification systems are useful to help predict the success of adhesiolysis for a given woman (Al-Inany, 2001).

Preoperative

PATIENT EVALUATION

Although hysteroscopy and saline-infusion sonography (SIS) both can identify adhesions accurately, hysterosalpingography (HSG) is preferred initially because it allows concurrent assessment of tubal patency. However, after adhesions have been noted, diagnostic hysteroscopy is recommended to assess the thickness and density of these bands (Fayez, 1987).

Additionally, completion of fertility assessment, including semen analysis and assessment of ovulation, is recommended prior to surgery to help predict the chances of conception following the procedure.

CONSENT

In general, hysteroscopic adhesiolysis is an effective tool to correct menstrual disorders and improve fertility in women with uterine adhesions (Valle, 2003; see also Chap 18, Diagnosis and Treatment). Although overall cumulative delivery rates in those with no

other fertility factors ranges from 60 to 70 percent, lower rates generally are associated with more severe disease (Pabuccu, 1997; Zikopoulos, 2004). In addition, pregnancies following surgery may be complicated by placenta accreta or increta or by preterm labor (Dmowski, 1969).

The complications of intrauterine adhesiolysis mirror those for operative hysteroscopy. However, the risk of uterine perforation may be increased. For this reason, patients also should be consented for diagnostic laparoscopy.

PATIENT PREPARATION

As with most operative hysteroscopic procedures, antibiotic prophylaxis is warranted. A and a first- or second-generation cephalosporin or other suitable antibiotic is appropriate. Additionally, laminaria tents or misoprostol may be used preoperatively to ease cervical dilatation (see Section 41-35, Hysteroscopy).

Intraoperative

Surgical Steps

1. **Anesthesia and Patient Positioning.** Hysteroscopic lysis of adhesions typically is a day-surgery procedure performed under general anesthesia. The woman is placed in dorsal lithotomy position, the vaginal is surgically prepared, and a Foley catheter is inserted.

2. **Medium Selection.** The choice of distending medium is dictated by the tool used. Sharp transection with scissors, neodymium:yttrium-aluminum-garnet (Nd:YAG) laser, or bipolar instrument can be performed in any liquid medium. However, thick adhesions often require resection rather than division, and they are severed close to the myometrium. Thus, the potential for creation of large denuded areas and fluid intravasation is great. Accordingly, for many surgeons, 0.9-percent saline is preferred because hyponatremia is avoided if fluid overload does develop (see Section 41-35, Hysteroscopy).

3. **Concurrent Laparoscopy.** Because of the increased risk of uterine perforation in those with more severe obliteration of the cavity, adjunctive laparoscopy may guide surgeons as to instrument proximity to the uterine serosa. The decision to use a laparoscope is individualized, and its placement follows the steps described in Section 41-28, Laparoscopy.

4. **Cervical dilatation.** Using a Pratt or other suitable dilators, the surgeon dilates the cervix as described in Section 41-16, Sharp Dilatation and Curettage.

5. **Instrument Insertion.** The distending medium flow is begun, and the operative hysteroscope is inserted into the endocervical canal under direct visualization. On entering the endometrial cavity, a panoramic inspection is performed first to identify adhesions.

6. **Approach to Lysis.** In general, a systematic approach to adhesiolysis begins with either blunt or sharp disruption of the most central adhesions and moves gradually to reach the most lateral. The size and qualities of adhesions may vary. Thin endometrial adhesions usually can be disrupted with blunt force from the hysteroscopic sheath alone. More commonly, myofibrous and fibrous adhesions are denser and may require complete resection.

   Adhesiolysis is continued until the endometrial cavity is restored to normal size and contour, and the tubal ostia are seen. Importantly, procedures may require termination prior to this if significant fluid volume deficits are reached (see Section 41-35, Hysteroscopy).

7. **Chromotubation.** At completion of adhesiolysis, transcervical chromotubation is performed to document tubal patency.

8. **Mechanical Uterine Distention.** Mechanical endometrial cavity distention has been used to prevent treated areas from adhering following surgery. Either an intrauterine device (IUD), placed for 3 months, or an 8F pediatric Foley catheter balloon, used for 10 days, may be chosen. In comparison of the two, Orhue and colleagues (2003) noted fewer new adhesions and greater pregnancy rates in woman using the balloon. If a Foley balloon is placed, antibiotic prophylaxis with either doxycycline 100 mg orally twice daily or other appropriate antibiotic is recommended during balloon use.

Postoperative

Recovery from hysteroscopic resection is rapid and typically without complication. Patients may resume normal activities and diet as tolerated.

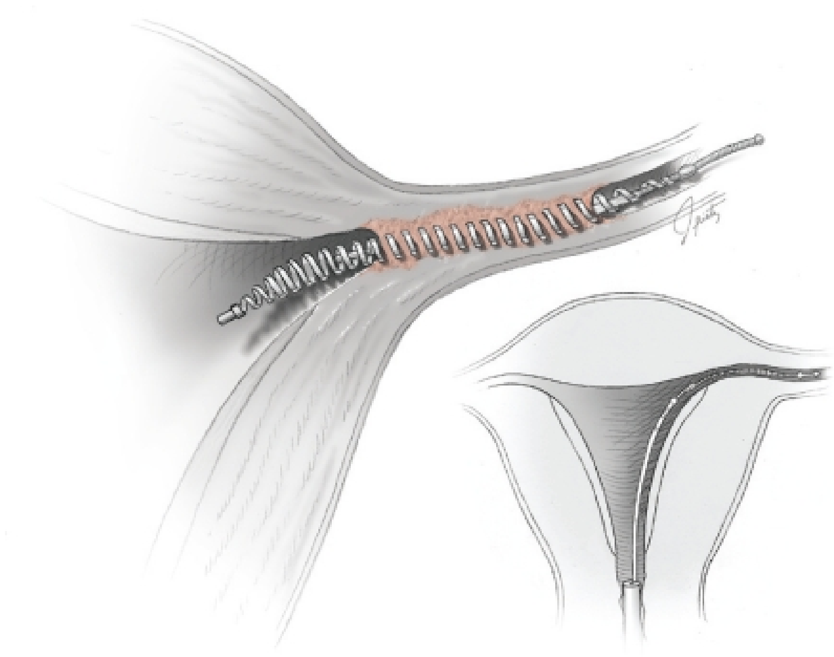
To stimulate endometrial proliferation and prevent adhesion re-formation, oral estrogen administration has proved effective. Although several regimens can be used, we prescribe 2 mg of estradiol orally for 30 days following adhesiolysis.

New adhesions can form following adhesiolysis. In their early stages, these bands are thinner and thus more amenable to successful resection. For this reason, another hysteroscopy or HSG typically is performed at 3 months following the initial resection. If significant new adhesions are found, a repeat surgical lysis of adhesions is planned. To allow adequate uterine healing, attempts at pregnancy by the patient should be delayed for 2 to 3 months.

41-42 HYSTEROSCOPIC PLACEMENT OF ESSURE MICROINSERTS

Hysteroscopic placement of the Essure Permanent Birth Control System (Conceptus, Inc., San Carlos, CA) is a transcervical method of female sterilization. With this procedure, a coil device, termed a microinsert, is inserted into the lumen of proximal section of each fallopian tube. Once in place and released from its delivery catheter, the microinsert expands and anchors itself in the fallopian tube (Fig. 41-42.1). Over time, synthetic fibers within the microinsert incite a chronic inflammatory response and local tissue ingrowth from the surrounding tube. This ingrowth leads to complete tubal lumen occlusion, which is documented by hysterosalpingography (HSG) at 3 months following surgery.

FIGURE 41-42.1



Source: Schorge JO, Schaffer JI, Halvorson LM, Hoffman BL, Bradshaw KD, Cunningham FG: *Williams Gynecology*: http://www.accessmedicine.com

Microinsert placement and ingrowth of tissue.

As with any permanent birth control method, candidates should be confident in their decision for sterilization. Contraindications include pregnancy or pregnancy termination within the prior 6 weeks, recent pelvic infection, known tubal occlusion, and allergy to nickel or radiographic contrast media.

Preoperative

PATIENT EVALUATION

Pregnancy should be excluded prior to sterilization using a serum or urine beta human chorionic gonadotropin β-hCG test.

CONSENT

For many women, the Essure System is a safe and effective method of birth control, with efficacy rates comparable with current laparoscopic sterilization rates (Magos, 2004). However, microinsert placement may not be possible in all women due to tubal ostium stenosis or spasm or an inability to visualize the ostia (Cooper, 2003). Rates of successful placement average 88 to 95 percent (Kerin, 2003; Ubeda, 2004).

In general, complications of Essure System placement are similar to those of hysteroscopy. However, rates of fluid volume overload are low because in most cases procedure lengths are short (15 to 30 minutes), and opening of endometrial vascular channels is minimal. Uterine or tubal perforation has been noted. Rates approximate 1 to 2 percent and in most cases are clinically insignificant (Kerin, 2003; Cooper, 2003).

PATIENT PREPARATION

Because menstrual bleeding and a thick endometrium can impair identification of tubal ostia, this procedure typically is performed during the early proliferative phase of the menstrual cycle. This also decreases the chance of an unidentified luteal phase pregnancy.

Preoperative analgesia may be considered and typically consists of a nonsteroidal anti-inflammatory drug given 30 to 60 minutes before the procedure.

Intraoperative

INSTRUMENTS

The Essure System is disposable and contains a handle, delivery catheter, release catheter, delivery wire, and microinserts. Each microinsert is attached to the end of a delivery wire, which is housed within a release catheter. In turn, the release catheter is surrounded by a delivery catheter.

Surgical Steps

1. **Anesthesia and Patient Positioning.** Hysteroscopic placement of the Essure System can be performed in an outpatient setting under local analgesia with or without intravenous sedation. Alternatively, a day-surgery setting using general anesthesia may be selected. The patient is placed in dorsal lithotomy position, and the vagina is surgically prepared.

2. **Media Selection.** Electrosurgery is not required, and therefore, 0.9-percent saline is used commonly to avoid the increased expense and risk of hyponatremia associated with nonelectrolyte solutions. As with any hysteroscopic procedure, accurate calculation of fluid volume deficits during the procedure is essential (see Section 41-35, Hysteroscopy).

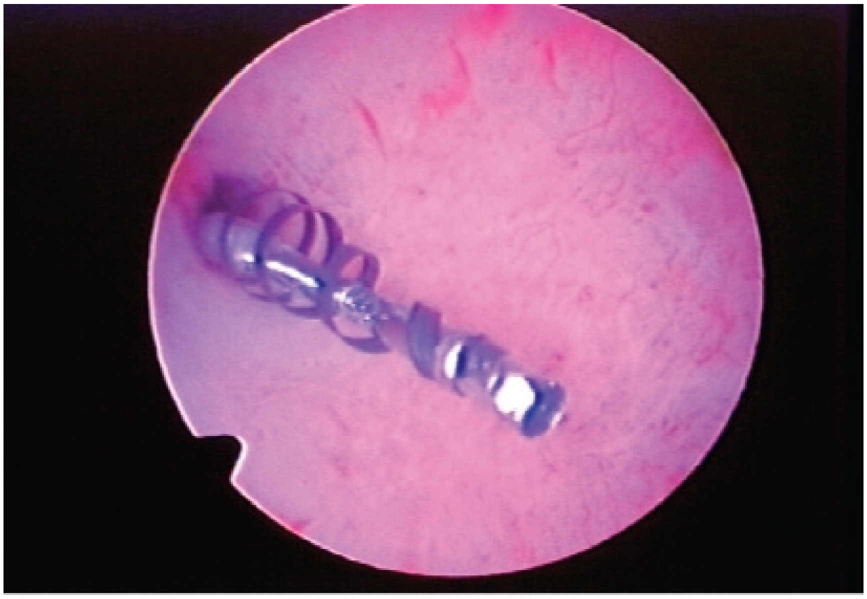
3. **Hysteroscope Insertion.** Vaginal retractors or a speculum provides access to the cervix, and a tenaculum may be used for adequate cervical traction to insert the hysteroscope. Depending on the diameter of the operative hysteroscope, cervical dilatation may or may not be required, as described in Section 41-16, Sharp Dilatation and Curettage. A 12- to 30-degree hysteroscope is preferred to provide easily visualization of the cornua, and a 5F operating channel is required.

4. **Ostia Identification.** Requisite for completion of the procedure, both tubal ostia must be visualized.

5. **Microinsert Delivery.** The outermost catheter of the system, the delivery catheter, is threaded through the operating channel of the hysteroscope. Its tip is inserted into one tubal ostium. The delivery catheter is retracted into the Essure System handle, and an inner cannula, the release catheter, is seen. Next, as the release catheter is retracted, the microinsert begins to uncoil. Ideally, four to eight coils of the microinsert trail into the endometrial cavity (Fig. 41-42.2). As a final step, a guidewire that is attached to the distal end of the microinsert is detached and retracted.

   These steps are repeated at the opposite ostium.

FIGURE 41-42.2



Source: Schorge JO, Schaffer JI, Halvorson LM, Hoffman BL, Bradshaw KD, Cunningham FG: *Williams Gynecology*: http://www.accessmedicine.com

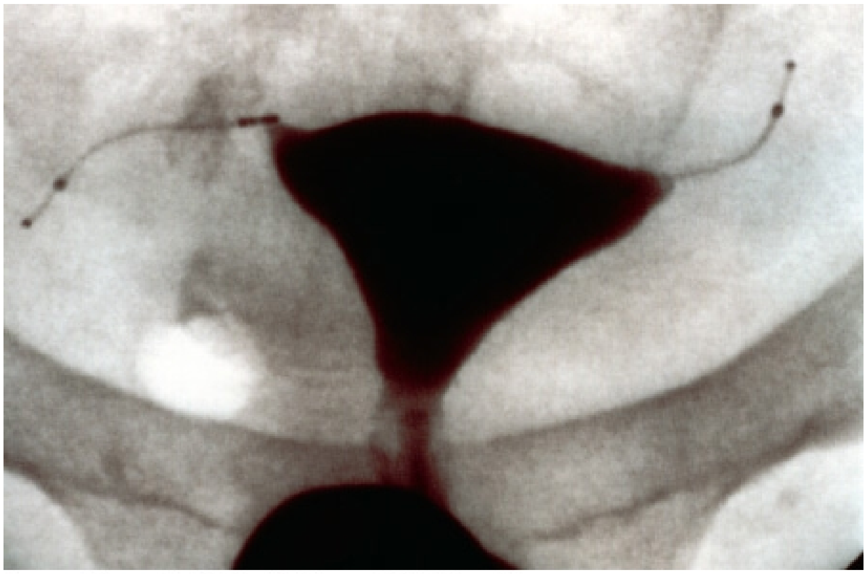
Hysteroscopic photograph of Essure microinsert coils within the tubal ostium. (Courtesy of Conceptus, Inc.)

Postoperative

Patients typically resume normal diet and activity within the first 24 hours following surgery. Cramping is common within the first few days, and light spotting or bleeding may be noted during the week following surgery.

To document complete tubal occlusion, HSG is performed at 3 months following insertion (Fig. 41-42.3). Until this time, an alternative method of contraception should be used. Rarely, in those with correct placement, tubal occlusion may not be complete at 3 months, and a second HSG at 6 months may be required to document sterilization.

FIGURE 41-42.3



Hysterosalpingography displaying correct Essure microinsert placement. (Courtesy of Conceptus, Inc.).

In addition, microinserts can be expelled. Thus, if no device is identified, or if 18 or more coils are seen trailing into the uterine cavity during HSG, then the microinsert should be replaced or alternative method of contraception used (Magos, 2004).

Essure microinserts can conduct electrical energy. Therefore, it is recommended that direct visualization of the inserts or the cornual area be obtain hysteroscopically or laparoscopically prior to any subsequent electrosurgical procedures near the inserts.

42-1 DIAGNOSTIC AND OPERATIVE CYSTOSCOPY AND URETHROSCOPY

The lower urinary tract may be injured during gynecologic surgery. Therefore, diagnostic cystoscopic evaluation typically is warranted following procedures in which the bladder and ureters have been placed at risk. Operative cystoscopy is within the scope of many gynecologists for the passage of ureteral stents, lesion biopsy, and foreign-body removal. Of these, ureteral stenting may be indicated to assess ureteral patency following gynecologic surgery or to delineate the ureter's course in patients with abnormal pelvic anatomy.

Rigid and flexible cystoscopes are available, although in gynecology a rigid scope typically is used. A cystoscope is composed of a sheath, bridge, telescope, and obturator. The sheath contains a port for fluid infusion and a second port for fluid egress. For office cystoscopy, a sheath measuring 17F affords greater comfort, whereas for operative cases, a 21F or wider-diameter cystoscope is preferred to allow rapid infusion of fluids. The sheath's end is sharp, and in patients in whom the urethral meatus is narrow, an obturator is placed inside the sheath and serves to introduce it smoothly. The bridge attaches to the proximal sheath and allows coupling between the telescope and sheath.

Several viewing angles are available and include 0-, 30-, and 70-degree optical views (Fig. 42-1.1). The 0-degree telescopes are used for urethroscopy. For cystoscopy, a 70-degree telescope is superior in providing the most comprehensive view of the lateral, anterior, and posterior walls; trigone; and ureteral orifices. To achieve a comparable view, a 30-degree scope requires additional manipulation. However, a 30-degree scope does offer advantages and allows surgeons greater flexibility because it can be used for either urethroscopy or cystoscopy during a given case. For operative cystoscopic cases in which instrument are passed down the sheath, a 30-degree scope must be used because with 0- and 70-degree scopes, operative instruments lie outside the field of view.

Cystoscopic optical views.

Preoperative

PATIENT EVALUATION

A significant incidence of bacteruria follows cystoscopy. Thus, prior to cystoscopy, urinary tract infection should be excluded.

CONSENT

If performed properly, complications of diagnostic cystoscopy are rare. Of these, infection is the most common.

PATIENT PREPARATION

Although evidence-based data are lacking for its use, oral antibiotic prophylaxis is commonly given postoperatively.

Intraoperative

Surgical Steps

1. **Distention Media.** The bladder must be distended adequately to fully visualization all surfaces, and for diagnostic purposes, saline or sterile water may be used. To ensure adequate medium flow, an infusion bag should be elevated significantly above the level of the symphysis. The volume needed may vary but is reached when bladder walls are not collapsing inward. Care must taken to avoid overdistending the bladder, which may result in temporary urinary retention. If the bladder is distended beyond its capacity, excess fluid will leak out the urethral meatus and around the scope rather than resulting in bladder rupture, which is rare.

2. **Indigo Carmine.** If intraoperative cystoscopy is performed to document ureteral patency Â½ to 1 ampule of indigo carmine is administered prior to the procedure.

3. **Anesthesia and Patient Positioning.** Cystoscopy may be performed in any lithotomy position with the legs positioned in stirrups. For office cystoscopy, 2-percent lidocaine jelly is instilled into the urethra 5 to 10 minutes prior to cystoscope insertion. For operative procedures, an additional 50 mL of 4-percent lidocaine solution is instilled into the bladder. The perineum and urethral meatus are surgically prepared.

4. **Cystoscopy.** The anterior urethral wall is very sensitive, and the sharp bevel edge, if directed anteriorly, may cause increased discomfort. Therefore, a cystoscope is inserted into the urethral meatus with the bevel directed posteriorly. Immediately following insertion into the meatus, media flow is started. The cystoscope is advanced to the bladder under direct visualization.

5. **Bladder Inspection.** On entry into the bladder, the cystoscope is withdrawn slowly until the bladder neck is identified. The cystoscope then is advanced and rotated 180 degrees. An air bubble is noted at the dome, which provides orientation for the remainder of the cystoscopic examination. The cystoscope then is withdrawn to the bladder neck and angled downward to provide a view of the trigone and both ureteral orifices. If ureteral patency is the topic of focus, brisk flow of indigo carmine should be seen from each orifice. Peristalsis of the ureteral orifice alone, without flow, is insufficient to document patency. Moreover, scant flow may indicate partial ureteral obstruction. Bladder walls are inspected by rotating the cystoscope until all surfaces have been evaluated. During inspection, digital elevation of the anterior vaginal wall is beneficial if pelvic organ prolapse is present.

6. **Operative Cystoscopy.** The operative instrument (biopsy or grasping forceps or scissors) is introduced through the operative port until viewed at the end of the cystoscope. Prior to instrument insertion, a rubber adapter cap is positioned over the operative port to create a watertight seal with the operative instrument. Once in view, the instrument and cystoscope are moved together as a unit toward the area of interest.

7. **Ureteral Stenting.** Ureteral stents may be placed at several junctures during surgery. They may be placed at the beginning of surgery and left through its duration to define anatomy in patients in whom the ureter is at surgical risk of injury. Alternatively, they may be placed intraoperatively to exclude ureteral injury. Finally, ureteral stents may be positioned and

left in place at the conclusion of surgery if ureteral injury is suspected or identified. Duration of postoperative stenting is variable and based on clinical indications.

Ureteral stents are available in a variety of sizes, and those ranging from 5F to 7F are used commonly. Stents vary in length from 12 to 30 cm, and a 24-cm length is appropriate for most adults. Generally, open-ended or whistle-tip stents are used to delineate anatomy in patients in whom the ureter is at surgical risk or to exclude obstruction. Double- or single-pigtail stents are used in situations in which prolonged ureteral drainage is required.

8. **To Exclude Ureteral Obstruction.** An open-ended or whistle-tip stent is threaded through the operative channel of a 30-degree cystoscope and into the field of view. By advancing both the stent and cystoscope toward the orifice, the stent is passed into the ureteral orifice. After the stent has entered the orifice, it is threaded and advanced manually. Alternatively, an AlberrÃin bridge may be used. This specialized bridging sheath allows deflection and guidance of a stent into an orifice. Once a stent is placed within the orifice, it is advanced past the level of suspected obstruction. If a stent is advanced easily, obstruction is excluded. In most gynecologic surgeries, this would not be higher than the pelvic brim. When passing a stent, undue pressure is avoided during advancement to avoid ureteral perforation.

9. **To Delineate Anatomy.** For this purpose, the stent is advanced until resistance is met, which indicates that the renal pelvis has been reached. The stent is tied securely to the transurethral catheter and drains into the Foley bag. At the conclusion of surgery, the stent is removed.

10. **Ureteral Stenting.** In patients in whom a ureteral stent is required postoperatively, a double-pigtail type stent is used. The proximal and distal coils of this stent prevent renal pelvis injury and secure placement in the bladder, respectively.

    A guidewire is first threaded into the ureteral orifice and passed to the renal pelvis. The pigtail stent then is placed over the guidewire and advanced by a pusher device until the distal end enters the bladder. The guidewire is removed, allowing the ends to coil in the renal pelvis and bladder, respectively.

11. **Biopsy.** Mucosal lesions can be biopsed with a minimal amount of risk and discomfort to the patient. A biopsy instrument is introduced into the cystoscope's operative port and brought into the operative field. With the instrument directly in the field of view, the cystoscope is moved directly to the lesion. Biopsy is performed, and the cystoscope and instrument are withdrawn through the urethra together. In this way, a biopsy specimen is not pulled through the sheath and possibly lost. Bleeding usually is minor and will stop by itself. For brisk bleeding, electrosurgical coagulation can be used if a nonconducting solution was selected as the distention medium.

12. **Removal of Foreign Bodies.** Foreign bodies, such as stones, are removed using the same technique as biopsy. The instrument is used to grasp the foreign body and then is removed together with the cystoscope.

13. **Suprapubic Teloscopy.** Suprapubic teloscopy is a technique used to visualize the bladder through an abdominal approach. We have found this technique to be valuable when the ureters must be assessed during a difficult cesarean delivery or during a laparotomy in which a woman has not been positioned to allow easy cystoscopic access to the urethra. The bladder is distended using the transurethral Foley catheter until the bladder wall is tense. A wide purse-string using 2-0 absorbable suture then is placed at the bladder dome, taking deep bites into the bladder muscularis (Fig. 42-1.2). The two suture ends are elevated but held loosely. A small stab incision then is made in the purse-string's center, and a cystoscope is introduced into the bladder. For suprapubic teloscopy, a 30-degree cystoscope is most effective. The two suture ends then are pulled up and held tightly to prevent escape of the distending fluid. To allow visualization of the trigone and ureteral orifices, the Foley bulb is deflated but left in place. Indigo carmine is given if necessary to document ureteral efflux. If the ureteral orifices still cannot be visualized, the bladder incision is extended to allow direct visualization. At the conclusion of the teloscopy, the cystoscope is removed, and the purse-string suture is tied, closing the cystotomy.

Suprapubic teloscopy.

Postoperative

Office cystoscopy does not require specific postoperative management except for prophylactic antibiotics. With operative cystoscopy, hematuria may develop, generally clears within a few days, and is considered significant only if associated with symptomatic anemia. With long-term ureteral stenting, additional complications may include ureteral spasm, which typically presents as back pain.

42-2 BURCH COLPOSUSPENSION

Abdominal-approach anti-incontinence procedures attempt to correct stress urinary incontinence (SUI) by stabilizing the anterior vaginal wall and urethrovesical junction in a retropubic location. Specifically, the Burch procedure, also known as retropubic urethropexy, uses the strength of the iliopectineal ligament (Cooper ligament) to stabilize the anterior vaginal wall and anchor it to the musculoskeletal framework of the pelvis (see Fig. 38-25).

The Burch colposuspension usually is performed through a Pfannenstiel or Cherney incision (see Section 41-2, Pfannenstiel Incision). More recently, however, some surgeons have introduced laparoscopic approaches that use suture or mesh to affix the paravaginal tissues to Cooper ligament (Ankardal, 2004; Zullo, 2004). However, compared with open Burch colposuspension, laparoscopic approaches have proved less effective (el Toukhy, 2001; Moehrer, 2002).

Preoperative

PATIENT EVALUATION

Prior to surgery, patients undergo complete urogynecologic evaluation. Urodynamic testing is recommended to differentiate stress and urge incontinence as well as to assess bladder capacity and voiding patterns (see Chap. 23, Diagnostic Testing).

Many women with SUI also may have associated pelvic organ prolapse. For this reason, other indicated pelvic reconstructive surgeries commonly accompany Burch colposuspension.

In women requiring hysterectomy, hysterectomy does not appear to improve or worsen success rates of Burch colposuspension (Bai, 2004; Meltomaa, 2001). Hysterectomy in this setting may be performed either vaginally or abdominally without significant differences in perioperative complications (Sze, 1997).

CONSENT

For most women with SUI, Burch colposuspension offers a safe, effective long-term treatment for incontinence. Success rates vary based on how success is defined, but it is generally believed that this operation provides symptomatic cure in approximately 85 percent of patients. Surgical risks compare similarly with other surgeries for SUI (Green, 2005; Lapitan, 2003). Intraoperative complications are rare and may include ureteral injury, bladder perforation, and hemorrhage (Galloway, 1987; Ladwig, 2004).

Complications, however, are not uncommon postoperatively and may include urinary tract or wound infection, voiding dysfunction, de novo urinary urgency, and pelvic organ prolapse, primarily enterocele formation (Alcalay, 1995; Demirci, 2000, 2001; Norton, 2006). Overcorrection of the urethrovesical angle has been suggested as a cause of these long-term urinary and prolapse complications.

Antibiotic Prophylaxis

Prior to Burch colposuspension, administration of antibiotics preoperatively is warranted. Bhatia (1989) showed significantly less febrile morbidity in women given 1-g doses of cefazolin intravenously before, during, and 8 hours after colposuspension compared with women receiving no prophylaxis.

Intraoperative

Surgical Steps

1. **Anesthesia and Patient Positioning.** The patient is placed supine with legs in Allen stirrups (Allen Medical Systems, Acton, MA) in low lithotomy position. The abdomen and vagina are surgically prepared, and a Foley catheter is placed.

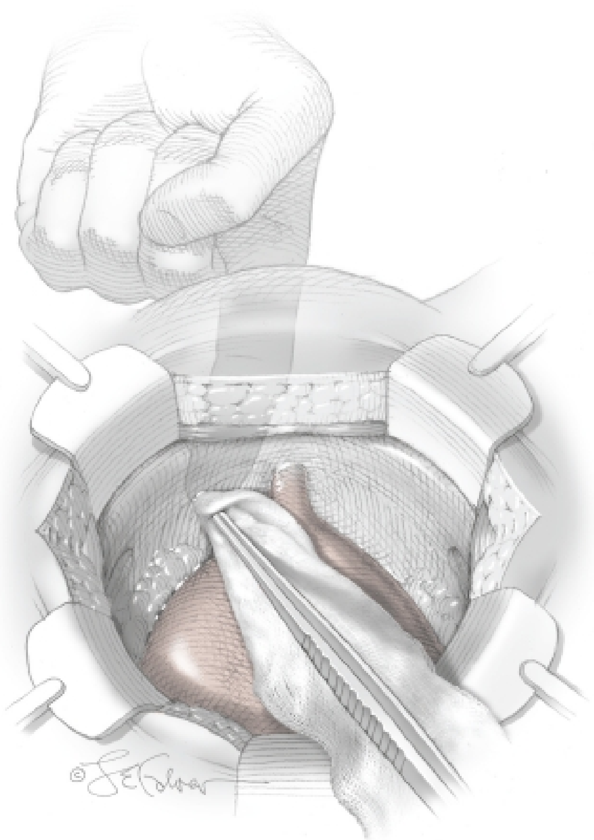
2. **Abdominal Incision.** A low Pfannenstiel or Cherney incision is performed (see Section 41-2, Pfannenstiel Incision). Surgery in the space of Retzius is easier to accomplish if the transverse incision is placed low on the abdomen, approximately 1 cm above the upper border of the pubic symphysis. If hysterectomy, culdoplasty, or other intraperitoneal procedure is planned, the peritoneum is entered and concurrent surgery completed prior to beginning colposuspension.

3. **Entry into the Space of Retzius.** On closure of the peritoneum, the avascular plane between the pubic bone and loose areolar tissue, that is, the space of Retzius, must be exposed. To enter this space, the fingers of one hand gently dissect along the cephalad surface of the pubic bone. Alternatively, gentle sponge dissection can be used to open this space (Fig. 42-2.1). The loose areolar tissue found behind the symphysis will separate easily from the bone. However, if the wrong plane is entered, bleeding can occur. Direct exposure of the back of the pubic bone ensures that the correct space has been entered. The bladder and urethra gently pull downward and away from the pubic bone, and the space of Retzius opens.

   In those with prior surgery, sharp dissection may be required. Dissection begins with the curved tips of the Metzenbaum scissors directly on the pubic bone and progresses dorsally until the space is exposed. Clips and sutures can be used to control bleeding vessels.

   During space of Retzius dissection, the obturator canal should be identified early to avoid neurovascular injury to the obturator vessels and nerves (see Fig. 38-25). The iliopectineal ligament (Cooper ligament) is identified as the space is opened.

FIGURE 42-2.1



Source: Schorge JO, Schaffer JI, Halvorson LM, Hoffman BL, Bradshaw KD, Cunningham FG: *Williams Gynecology*: http://www.accessmedicine.com

Entry into the space of Retzius.

4. **Exposing the Anterior Vaginal Wall.** Following creation of this space, the index and middle fingers of the surgeon's nondominant hand are place in the vagina. With one on each side, the finger pads straddle the urethra and push the vagina ventrally. This maneuver alone will clear much of the fat off the anterior vaginal wall.

   If necessary, the surgeon can use a Kitner (peanut) sponge or gauze sponge stick on either side of the urethra to wipe the fatty connective tissue laterally. Upward pressure by the vaginal fingers and downward, lateral pressure during this blunt separation reveal the white glistening anterior vaginal wall. Importantly, to protect the delicate urethral musculature, this dissection should remain lateral to the urethra.

   Dissection may bring laceration of vessels within the Santorini plexus of paravaginal veins and a risk for significant bleeding. This is controlled easily with upward pressure from the vaginal fingers. Identified vessels can be sealed with electrosurgical coagulation, ligation, or placement of vascular clips.

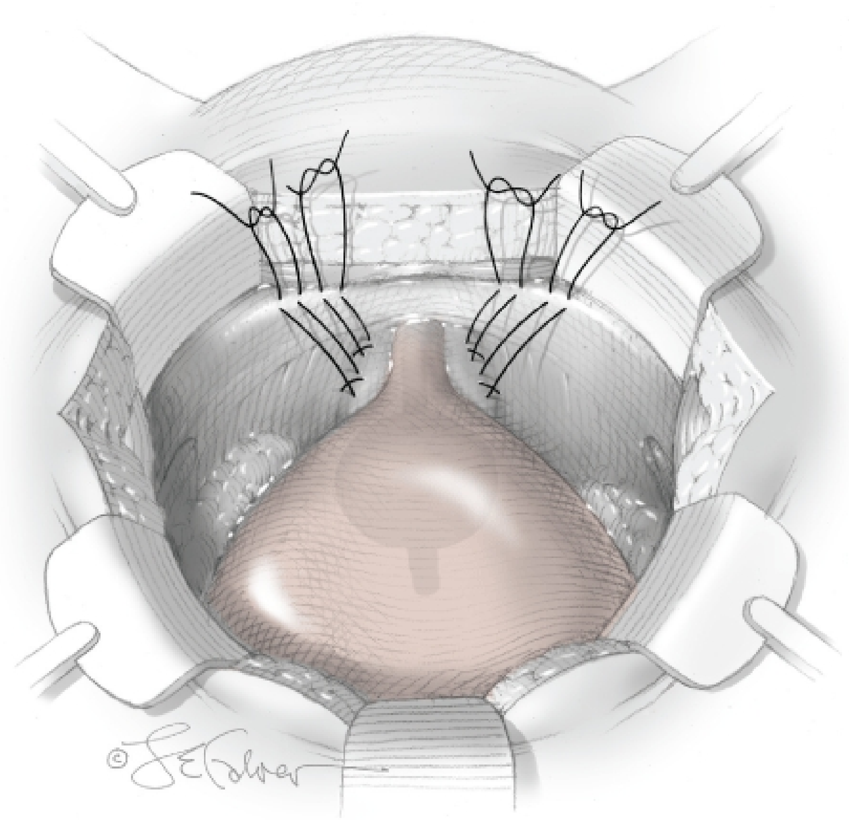
5. **Identifying the Urethrovesical Junction.** The urethrovesical junction is identified to aid correct suture placement. This site can be found by using the surgeon's vaginal hand to position the Foley catheter balloon at the bladder neck. This should be done without pulling the Foley catheter. Tension may drag the bladder into the operative field and increase the risk of suture entry into the bladder.

6. **Suture Placement.** A double-armed 2-0 suture of permanent material is placed laterally on each side of the urethra. The

surgeon's vaginal finger is pressed upward to expose the appropriate area, and the needle point is directed toward that finger. A thimble may be used to avoid needlestick injury. A first suture is placed 2 cm lateral to the urethrovesical junction, and a second suture is placed 2 cm lateral to the proximal third of the urethra. With these stitches, a figure-of-eight suture is used to incorporate a wedge of tissue for support (Fig. 42-2.2). Stitches should incorporate the vaginal muscularis but not the epithelium. Identical sutures are then placed on the opposite side of the urethra.

Both ends of each suture next are placed through the nearest point of the ipsilateral iliopectineal ligament. Slack is removed from each suture, and knots are tied above the ligament. With knot securing, a surgeon invariably creates suture bridges. These should stabilize but not elevate the anterior vaginal wall and urethrovesical junction.

FIGURE 42-2.2



Source: Schorge JO, Schaffer JI, Halvorson LM, Hoffman BL, Bradshaw KD, Cunningham FG: *Williams Gynecology*: http://www.accessmedicine.com

Suture placement.

7. **Cystoscopy.** Following suture ligation, Â½ or 1 ampule of indigo carmine is given intravenously. and cystoscopy is performed. This allows identification and removal of any errant sutures that may traverse the bladder mucosa. Moreover, it enables the surgeon to inspect ureteral orifices and document flow as a means to exclude intraoperative ureteral injury.

8. **Catheterization.** At completion of colposuspension, the Foley catheter may remain and drain the bladder. Alternatively, a suprapubic catheter may be placed. In studies, investigators have compared the two and found no differences in incontinence procedure success rates, length of hospitalization, or rates of infection. Urethral catheterization, however, was linked with a shorter duration of catheterization but also greater patient discomfort (Dunn, 2005; Theofrastous, 2002).

9. **Incision Closure.** The abdominal wall fascia is closed in a running fashion with 0-gauge delayed-absorbable suture. The skin is closed using a running subcuticular suture with 4-0 delayed-absorbable material or other suitable skin closure method (see Chap 40, Subcuticular Suturing).

POSTOPERATIVE

In general, recovery follows that associated with laparotomy and varies depending on concurrent surgeries and incision size. A voiding trial as described in Chapter 39, Voiding Trials is performed prior to hospital discharge.

42-3 TENSION-FREE VAGINAL TAPE

The tension-free vaginal tape procedure (TVT) is the most commonly performed operation worldwide for stress urinary incontinence. The procedure is one of the most widely studied anti-incontinence operations, and 5-year cure rates approximate 85 percent. The TVT procedure also has become the prototype for a host of other anti-incontinence operations (SPARC Sling System, American Medical Systems, TOT [transobturator tape], TVT-O [tension-free vaginal tape]). These are all based on the concept that midurethral support is vital to continence.

Tension-free vaginal tape placement is indicated for stress urinary incontinence (SUI) secondary to urethral hypermobility or intrinsic sphincteric deficiency (see Chap 23, Midurethral Slings). It is used for primary cases as well as for those who have had prior anti-incontinence procedures.

During TVT, a permanent sling material is placed underneath the midurethra and brought behind the pubic bone and through the space of Retzius and anterior abdominal wall. The TVT needle is placed blindly through the space of Retzius, and significant bleeding is a risk. A modification of the TVT, the TOT (see Section 42-4, Transobturator Tape Sling) was developed to avoid hemorrhage in this space. However, TVT remains the primary standard operation for SUI.

The TVT device consists of a permanent polypropylene mesh covered with a plastic sheath that is removed after the mesh is placed. The plastic sheath is believed to prevent bacterial contamination of the mesh as it passes through the vagina and to protect the mesh from being damaged during passage. Each end of the mesh is attached to a disposable metal needle that is connected to a reusable metal introducer during placement. A metal catheter guide is used to displace the urethra away from the needle during the procedure.

Preoperative

PATIENT EVALUATION

Prior to performing a TVT procedure, a diagnosis of SUI must be made. A woman should have bothersome symptoms of urine leakage with cough, sneeze, activity, or increased intra-abdominal pressure. A urodynamic evaluation should be performed, and leakage with increases in intra-abdominal pressure in the absence of detrusor contractions should be documented (see Chap. 23, Pressure Flowmetry). In some women, symptoms do not correlate with objective findings of urine loss with stress. For these individuals, a surgical procedure should not be performed. Stress urinary incontinence may not be present, and surgery may fail to improve or may aggravate symptoms. An exception might be a woman with pelvic organ prolapse that is obstructing the urethra. In these women, the prolapse should be replaced during urodynamic testing to attempt to document latent or potential stress incontinence.

CONSENT

Postoperatively, consent process for TVT should include an honest discussion of outcomes. At best, the 5-year cure rate is 85 percent, with another 10 percent significantly improved. However, some patients will develop postoperative urge incontinence, and others will develop bothersome voiding dysfunction. Additionally, with time and aging, incontinence may recur secondary to factors not related to urethral support.

Intraoperative complications include hemorrhage, bladder perforation, and bowel injury. Major vessels are injured in less than 1 percent of patients.

Postoperatively, short-term complications of the procedure include incomplete bladder emptying requiring drainage with a Foley catheter or intermittent self-catheterization for several days. A small percentage of patients will develop long-term urinary retention requiring reoperation for excision or removal of the tape (see Section 42-8, Midurethral Sling Release). In patients who require excision or removal of a piece of the tape, continence rates decrease. The TVT procedure is associated with a learning curve, and urinary retention rates decrease as the number of cases a physician performs increases. Following surgery, vaginal mesh erosion may develop as an early or late complication. This is managed by simple excision of the eroding tape.

Intraoperative

Surgical Steps

1. **Anesthesia and Patient Positioning.** The procedure was described initially as an ambulatory surgical procedure performed under local anesthesia. However, it also can be performed with regional or general anesthesia. The rationale for local anesthesia is that a cough stress test can be performed after placement of the tape to allow for proper tension setting of the tape. If performed without other surgeries, TVT in most cases is a day-surgery procedure. The operation is performed in the high lithotomy position. The vagina is surgically prepared, and an 18F Foley catheter is placed to assist in deflection of the urethra during needle passage.

2. **Abdominal Incisions.** Two Â½-cm skin incisions are created 1 cm above the symphysis and 1 cm lateral to the midline. Although many surgeons incise the skin more laterally, we believe that midline incisions decrease the risk of major vessel injury and do not increase the risk of bladder perforation.

3. **Vaginal Incisions.** A midline incision is made sharply in the vaginal epithelium beginning 1 cm proximal to the urethral meatus and is extended 2 cm cephalad. Allis clamps are placed on the edges of the vaginal incision for traction. Using Metzenbaum scissors, bilateral submucosal tunnels are created beneath the vaginal epithelium on either side of the urethra. These tunnels extend several centimeters toward the ipsilateral pubic rami to allow placement of the TVT needle.

4. **Catheter Guide Placement.** A rigid guide is placed through the Foley catheter. During passage of the TVT needles, a surgical assistant uses the catheter guide to deflect the urethra to the contralateral side to prevent urethral injury.

5. **Mesh Placement.** The TVT needle and mesh are attached to the introducer. The needle is placed through the submucosal tunnel so that its point touches the front surface of the pubic rami (Fig. 42-3.1). A hand placed in the vagina then carefully guides the needle around the back of the rami and up toward the abdominal incision (Fig. 42-3.2). The needle always should be directly behind the pubic bone. Pressure is applied to the introducer handle with the other hand, but the vaginal hand always controls the needle's direction. The handle of the introducer always should remain parallel to the ground to avoid lateral excursion into vessels (Fig. 42-3.3). Additionally, after the needle is passed around the pubic rami and behind the symphysis, its tip always should be directed toward the abdominal wall. The bladder may be perforated if excessive pressure is applied and if the needle is aimed cephalad rather than toward the abdominal wall. Small changes in position of the hand applying pressure to the handle may lead to bladder perforation.

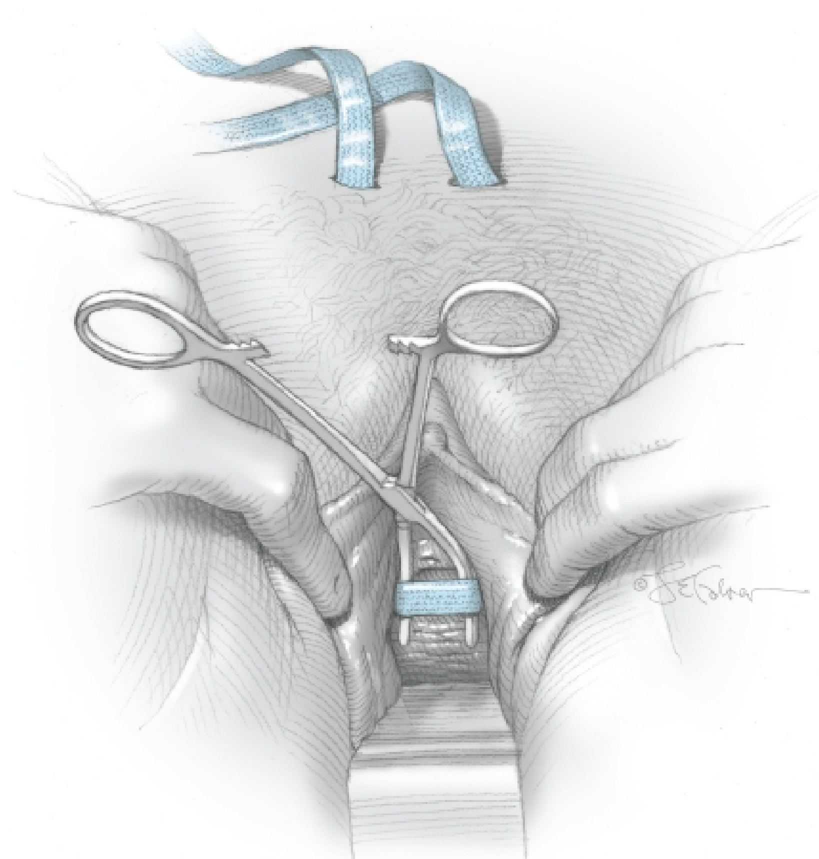
Correct and incorrect introducer positioning. **A.** Dark introducer, correct position. The tip is directed in the midline to a position behind the pubic bone. The handle is parallel to the ground. **B.** White introducer, incorrect position. The tip is directed laterally.

6. **Cystoscopy.** After the needle perforates the abdominal wall, the Foley catheter and catheter guide are removed. Cystoscopy is performed with a 70-degree cystoscope. During this, the bladder is distended with 200 to 300 mL of fluid, and inspection for perforation is completed. Generally, perforation will be obvious, and the TVT needle will be seen entering and exiting the bladder. In this situation, the needle is removed and replaced.

   After cystoscopy, the introducer is unscrewed from the needle, and the needle is brought through the abdominal wall. The needle is cut from the mesh, and the mesh is held with a hemostat. Next, a TVT needle is placed on the other side of the urethra, and cystoscopy is repeated.

7. **Setting Mesh Tension.** A hemostat is placed and opened between the urethra and mesh to act as a spacer and create distance between the mesh and urethra (Fig. 42-3.4). This spacing avoids excessive elevation of the urethra and lowers the risk for postoperative urinary retention.

FIGURE 42-3.4

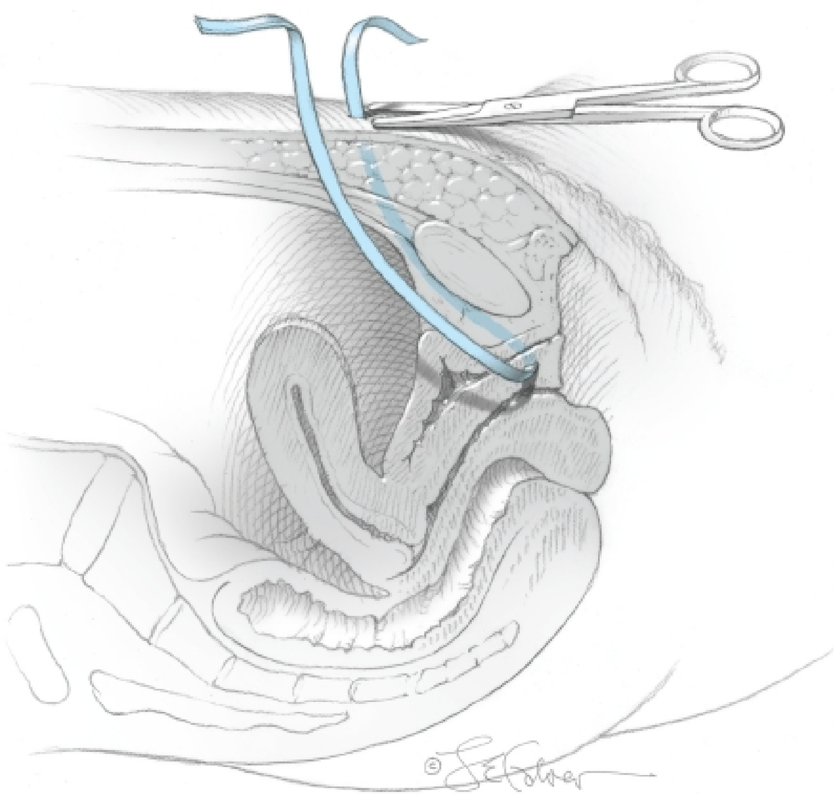


Source: Schorge JO, Schaffer JI, Halvorson LM, Hoffman BL, Bradshaw KD, Cunningham FG: *Williams Gynecology*: http://www.accessmedicine.com

Setting mesh tension.

8. **Sheath Removal.** An assistant surgeon then removes the plastic covering of the mesh while the surgeon holds the mesh at the desired distance from the urethra using the hemostat. The plastic covering should be removed with a minimal amount of tension to avoid mesh stretching. The mesh is trimmed at the abdominal incisions (Fig. 42-3.5).

FIGURE 42-3.5



Source: Schorge JO, Schaffer JI, Halvorson LM, Hoffman BL, Bradshaw KD, Cunningham FG: *Williams Gynecology*: http://www.accessmedicine.com

Sheath removal and tape trimming.

9. **Wound Closure.** The vaginal incision is closed in a running fashion with 2-0 delayed-absorbable suture. The abdominal incisions may be closed with skin adhesive or with a single interrupted 4-0 delayed-absorbable skin suture.

Postoperative

Prior to discharge from a day-surgery unit, an active voiding trial is performed (see Chap. 39, Voiding Trials). If the patient fails this trial, a Foley catheter remains. A second voiding trial can be repeated in a few days or at the surgeon's discretion. Alternatively, a woman can be taught self-catheterization. This is continued until postvoid residuals fall below 100 mL.

Normal diet and activity can resume during the first postoperative days. Intercourse, however, should be delayed until the vaginal incision is healed. The time to resumption of exercise and strenuous physical activity is controversial. A standard recommendation has been to delay these at least 2 months, although there are no data to support this. However, logic would suggest that this is a reasonable amount of time allow adequate healing.

42-4 TRANSOBTURATOR TAPE SLING

The transobturator tape (TOT) sling procedure is a variation of the midurethral sling procedures, which began with tension-free vaginal tape (TVT). The procedure is gaining popularity, although data regarding its long-term success are still not available. The procedure has several important differences from TVT, and there are also several modifications of the TOT procedure itself.

Generally, TOT is indicated for primary stress urinary incontinence (SUI) secondary to urethral hypermobility (see Chap 23, Midurethral Slings). It is currently not clear whether TOT will be of value in patients who have SUI secondary to intrinsic sphincteric deficiency.

During TOT procedures, a permanent sling material is placed bilaterally through the obturator fascia and extends underneath the midurethra. The entry point overlies the proximal tendon of the adductor longus muscle. Because of this entry approach, the space of Retzius is avoided. Bleeding in the space of Retzius is one of the primary complications of TVT, and avoidance of this space is an attractive TOT feature. Additionally, in patients who have had prior anti-incontinence procedures and have scarring in the space of Retzius, bladder perforation may be averted by avoiding dissection in this space.

Kits containing the required mesh and placement needles for TOT are produced by several companies, and each has its own modifications. The two major types of TOT procedures are defined by whether needle placement begins inside the vagina and is directed outward, termed an *in-to-out approach,* or starts outside and is directed inward, called an *out-to-in approach.* Currently, the out-to-in technique is performed more commonly and is described below.

Preoperative

PATIENT EVALUATION

Prior to surgery, patients undergo complete urogynecologic evaluation. Urodynamic testing is recommended to differentiate stress and urge incontinence. Many patients have mixed incontinence, and those whose stress symptoms predominate would be appropriate candidates.

Of note, caution must be exercised in patients who are Valsalva voiders. These women void with abdominal straining rather than with detrusor contraction and urethral relaxation. Most incontinence procedures prevent leakage by closing the urethra during cough or Valsalva maneuver. Therefore, these surgeries, when performed in women who rely on the Valsalva maneuver to urinate, often will results in voiding dysfunction.

CONSENT

As with other surgeries for incontinence, the major risks of this procedure are development of urge incontinence, voiding dysfunction, urinary retention, and failure to correct stress incontinence. Groin pain appears to be another potential postoperative problem. Long-term complications may be associated with the supporting mesh and include mesh erosion. Prior to surgery, patients should have realistic expectations and be informed of success rates in the literature as well as those of the individual surgeon. Moreover, the definition of *outcome success* varies from woman to woman. For example, in a patient with severe incontinence and 20 leakage episodes per day, improvement to 1 leakage episode every other day would be considered successful. However, in a woman with rare leakage, it may be more difficult to achieve an outcome considered satisfactory. For this reason, patient's expectations should be discussed prior to surgery.

Intraoperatively, there is some risk of bladder perforation, although it is believed to be significantly less than that with TVT. There also may be risk of urethral perforation. Lastly, inappropriate TOT trocar placement can lead to significant hemorrhage if major pelvic vessels are lacerated.

PATIENT PREPARATION

Bowel preparation is based on surgeon preference and on concurrent surgeries planned. Antibiotic prophylaxis is given.

Intraoperative

INSTRUMENTS

A TOT kit will contain two TOT needles and synthetic mesh tape (see Fig. 23-11). The TOT needle is designed to navigate the path from the entry point around the pubic rami. The needle then exits the vagina at a midpoint along the urethra's length.

A plastic sheath surrounds the mesh tape and allows the mesh to be pulled into position smoothly. However, once these plastic sheaths are removed, the mesh remains fixed in position.

Surgical Steps

1. **Anesthesia and Patient Positioning.** If performed without other surgeries, a TOT procedure in most cases is a day-surgery procedure. It is performed in high lithotomy position under general, regional, or local anesthesia. The vagina is surgically prepared, and a Foley catheter is placed to assist in determination of urethral location.

2. **Vaginal Incisions.** A midline incision is made sharply in the vaginal epithelium beginning 1 cm proximal to the urethral meatus and is extended 2 to 3 cm cephalad. Allis clamps are placed on the edges of the vaginal incision for traction. Using Metzenbaum scissors and blunt finger dissection, bilateral submucosal tunnels are created beneath the vaginal epithelium on either side of the urethra. These tunnels extend up to and behind the iliopubic rami.

3. **Thigh Incisions.** A 0.5- to 1-cm entry incision is made bilaterally in the thigh crease skin at a point 4 to 6 cm lateral to the clitoris, and at the site where the adductor longus insertion can be palpated.

4. **Mesh Placement.** The TOT needle is grasped, and the tip is placed in one of the thigh incisions (Fig. 42-4.1). The tip is directed cephalad until the obturator membrane is perforated, and a "popping" sensation is felt. A vaginal finger is placed in the ipsilateral vaginal tunnel and is positioned up to and behind the iliopubic rami. Using the curve of the TOT needle, the surgeon then directs the needle tip to the end of his finger and passes the needle into the vagina (Fig. 42-4.2). The TOT mesh is attached to the end of the needle, and the needle is withdrawn through the thigh incision (Fig. 42-4.3). The procedure is repeated on the other side.

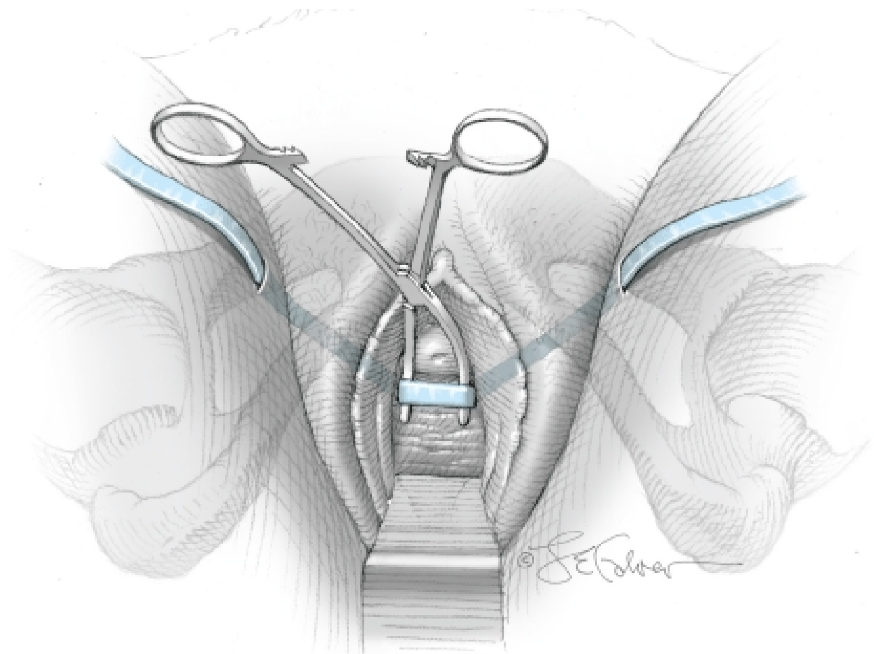
Tape placement.

5. **Setting Mesh Tension.** A hemostat is placed and opened between the urethra and mesh to act as a spacer and create distance between the mesh and the urethra (Fig. 42-4.4). This spacing avoids excessive elevation of the urethra and lowers the risk for postoperative urinary retention.

FIGURE 42-4.4



Source: Schorge JO, Schaffer JI, Halvorson LM, Hoffman BL, Bradshaw KD, Cunningham FG: *Williams Gynecology*: http://www.accessmedicine.com

Setting mesh tension.

6. **Sheath Removal.** An assistant surgeon then removes the plastic covering of the mesh through the thigh incision while the surgeon holds the mesh at the desired distance from the urethra using the hemostat. The plastic covering should be removed with a minimal amount of tension to avoid mesh stretching. The mesh is trimmed at the thigh incisions.

7. **Wound Closure.** The vaginal incision is closed in a running fashion with 2-0 delayed-absorbable suture. The thigh incisions may be closed with a single interrupted subcuticular suture with 4-0 delayed-absorbable suture or other suitable skin closure methods.

8. **Cystoscopy.** The procedure is marketed as one in which cystoscopy is not necessary. However, because bladder and urethral injury can occur, we recommend postprocedural cystoscopy.

Postoperative

Prior to discharge from the day-surgery unit, an active voiding trial is performed (see Chap. 39, Voiding Trials). If the patient fails this trial, a Foley catheter remains. A second voiding trial can be repeated in a few days or at the surgeon's discretion. Alternatively, a patient can be taught self-catheterization. This is continued until postvoid residuals fall below 100 mL.

Normal diet and activity can resume during the first postoperative days. Intercourse, however, should be delayed until the vaginal incision is healed. The time to resumption of exercise and strenuous physical activity is controversial. A standard recommendation has been to delay these at least 2 months, although there are no data to support this. However, logic would suggest that this is a reasonable amount of time allow adequate healing.

42-5 PUBOVAGINAL SLING

Pubovaginal sling is a standard procedure for stress urinary incontinence (SUI). Traditionally, it has been used for SUI stemming from intrinsic sphincteric deficiency, which is characterized by a nonmobile urethra, a low maximum urethral closing pressure, or

low Valsalva leak point pressure (see Chap. 23, Pubovaginal Slings). In addition, this procedure also may be indicated for patients with prior failed anti-incontinence operations. It is generally not employed in a woman having her first anti-incontinence operation.

In the past, different materials have been used for the sling. However, autologous fascia currently is preferred. Generally, autologous fascia is obtained from the rectus sheath, although fascia lata from the thigh alternatively may be used. With this surgery, a strip of fascia is placed at the bladder neck through the space of Retzius, and ends are secured above the rectus abdominis muscle.

Preoperative

PATIENT EVALUATION

As with other anti-incontinence procedures, patients require urogynecologic evaluation including urodynamic testing to confirm SUI and intrinsic sphincteric deficiency. Additionally, SUI often accompanies pelvic organ prolapse. Thus, the need for concurrent repair of associated prolapse should be assessed prior to surgery.

CONSENT

In addition to general surgical risks, patients should be counseled regarding the risk of recurrent incontinence and urinary retention following surgery.

PATIENT PREPARATION

Antibiotic prophylaxis with a first- or second-generation cephalosporin at the time surgery is recommended. Bowel preparation is performed the evening before surgery.

Intraoperative

Surgical Steps

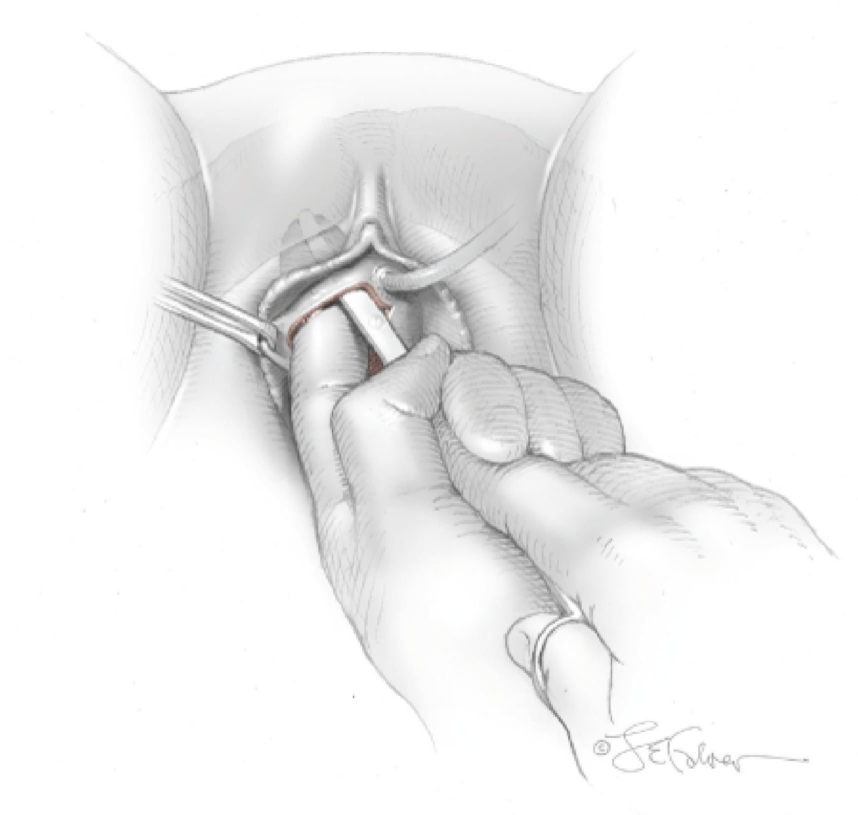
1. **Anesthesia and Patient Positioning.** Pubovaginal sling may be performed under general or regional anesthesia as an inpatient procedure. The patient is placed in a high lithotomy position, and the legs are held by candy-cane stirrups. The abdomen and vagina are surgically prepared, and a Foley catheter is placed.

2. **Graft Harvest.** A transverse skin incision is made 2 to 4 cm above the symphysis and should be large enough to allow removal of a fascial strip that measures, at minimum, 2 × 6 cm. The incision is carried down through subcutaneous tissue to the fascia.

   The fascia to be harvested is outlined and then dissected sharply and removed. Following removal, the strip is cleaned of fat and adventitial tissue. A helical stitch using 0-gauge polypropylene suture then is placed against the grain of the fascia at each end of the strip. These sutures are not tied. The fascial incision then is closed in a running fashion with 0-gauge delayed-absorbable suture.

3. **Vaginal Incision.** Two centimeters proximal to the urethral meatus, a 5- to 6-cm midline vertical incision is made sharply in the anterior vaginal wall. Sharp and blunt dissection is used to lift the vaginal epithelium off the underlying fibromuscular layer. The space of Retzius is entered bluntly or sharply bilaterally by penetrating the perineal membrane (Fig. 42-5.1). This membrane was previous termed the *deep fascia of the urogenital diaphragm* (see Fig. 38-28). The surgeon's finger should palpate the pubic bone in the space of Retzius (Fig. 42-5.2). Bleeding may be encountered, and this can be managed with compression or suturing.

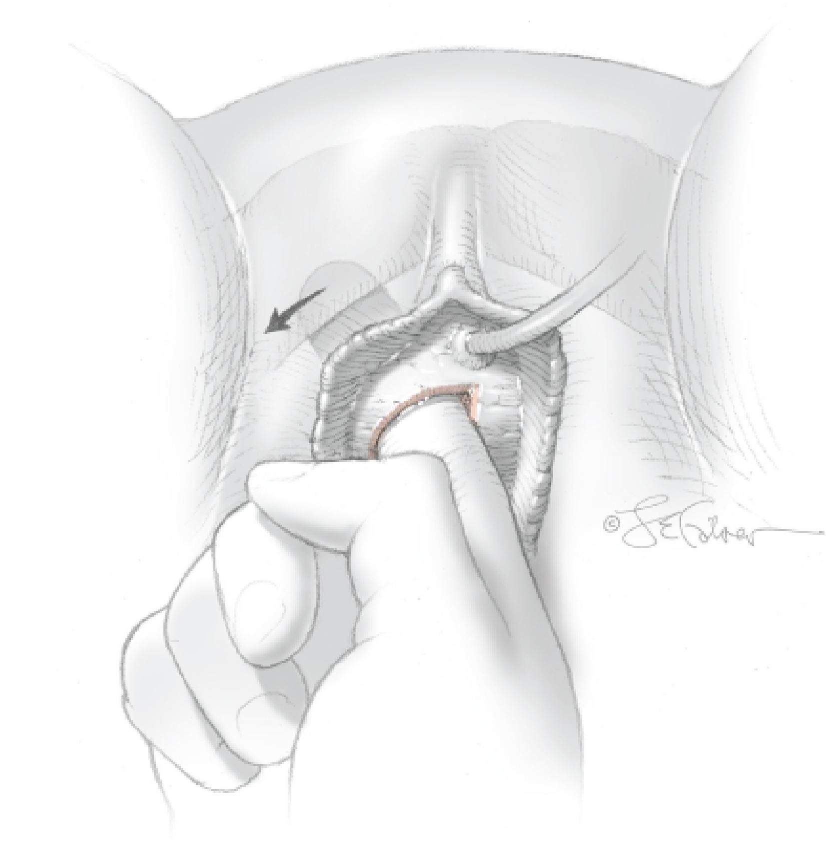
FIGURE 42-5.1



Source: Schorge JO, Schaffer JI, Halvorson LM, Hoffman BL, Bradshaw KD, Cunningham FG: *Williams Gynecology*: http://www.accessmedicine.com

Entry into the space of Retzius.

FIGURE 42-5.2



Source: Schorge JO, Schaffer JI, Halvorson LM, Hoffman BL, Bradshaw KD, Cunningham FG: *Williams Gynecology*: http://www.accessmedicine.com

Palpation of pubic bone.

4. **Fascia Placement.** A long dressing or packing forceps or needle ligature carrier is used from above to perforate the rectus sheath below the prior harvest incision. The instrument is placed against the back of the pubic bone and advanced toward the vagina. Concurrently, the surgeon guides the instrument to his or her finger within the space of Retzius (Fig. 42-5.3).

   The suture at one end of the fascial strip is grasped with the forceps and threaded up through the abdominal incision on one side of the urethra. A similar procedure is performed on the opposite side of the urethra with the other end of the sling. As a result, the fascial sling lies positioned below the bladder neck (Fig. 42-5.4). Three to four 2-0 delayed-absorbable sutures are used to fix the sling beneath the bladder neck to prevent movement.

FIGURE 42-5.3

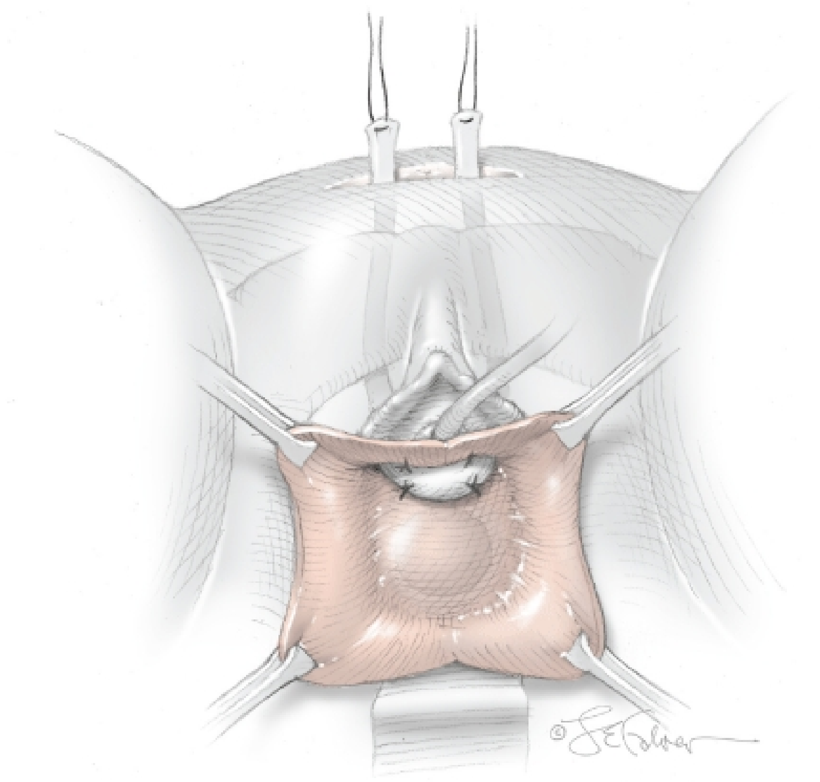
Fascial strip placement.

FIGURE 42-5.4



Source: Schorge JO, Schaffer JI, Halvorson LM, Hoffman BL, Bradshaw KD, Cunningham FG: *Williams Gynecology*: http://www.accessmedicine.com

Fascial sling sutured in place.

5. **Setting Sling Tension.** Sutures attached to the sling ends then are tied together above the rectus sheath. During knot tying, a space of two to three fingerbreadths is left between the knot and fascia to prevent bladder neck obstruction and urinary retention. After the knot is secured, there should be no upward angulation of the urethra or bladder neck.

6. **Cystoscopy.** Cystoscopy is performed to exclude bladder perforation and ureteral obstruction.

7. **Vaginal Incision.** The vaginal incision is closed with 2-0 delayed-absorbable suture in a running fashion. A Foley catheter is left in place. In the past it was common practice to insert a suprapubic tube. However, with a trend toward setting tension loosely on the sling, the risk of prolonged urinary retention is lowered, and suprapubic drainage therefore is not typically required.

8. **Abdominal Incision.** The abdominal incision is closed as described in Section 41-2, Pfannenstiel Incision.

Postoperative

In general, recovery follows that associated with laparotomy and depends heavily on incision size. A voiding trial as described in Chapter 39, Voiding Trials is performed prior to hospital discharge.

42-6 URETHRAL BULKING INJECTIONS

Injection of bulking agents into the urethral submucosa is one method available to treat stress urinary incontinence (SUI) resulting from intrinsic sphincter deficiency (ISD) (see Chap. 23, Periurethral Bulking Agents). Although mechanisms are not completely

clear, effectiveness may result from expansion of the urethral walls, which allows them to better approximate or *coapt* (Kershen, 2002). As a result, intraluminal resistance to flow is increased, and continence is restored (Winters, 1995). As another effect, injections elongate the functional urethra, and this may allow more even distribution of abdominal pressures across the proximal urethra to resist opening during stress (Monga, 1997).

Although traditionally recommended for treatment of SUI solely due to ISD, some evidence suggests that it can be used to treat SUI resulting from combined ISD and urethral hypermobility (Bent, 2001; Herschorn, 1997; Steele, 2000).

Urethral injection offers a cystoscopically assisted, minimally invasive treatment of SUI that can be performed in an office setting under local anesthesia and is associated with a low risk of complications. For these reasons, it is often chosen for women who wish to avoid surgery or who are not surgical candidates because of other health reasons. Urethral injections can be performed both peri- and transurethrally. The transurethral approach is used more commonly and allows for more accurate placement of the bulking agent (Faerber, 1998; Schulz, 2004).

Currently available agents in the United States approved for use include bovine collagen, autologous fat, and several synthetic agents. Of these, collagen is used most commonly in the United States.

Preoperative

PATIENT EVALUATION

Complex urodynamic testing with assessment of urethral structure and function should be completed. Maximum urethral closure pressure or leak point pressure is specifically evaluated (see Chap. 23, Multichannel Cystometrics). Additionally, urethral mobility should be assessed with Q-Tip testing or similar evaluation (see Fig. 23-8)

CONSENT

Patients should be informed that although success rates in general are lower than those for surgery, 1-year rates of curing or improving SUI range from 60 to 80 percent (Bent, 2001; Corcos, 2005; Lightner, 2002; Monga, 1995). Continence rates diminish with time, as would be intuitive with the breakdown of collagen and fat. However, Chrouser (2004) found similar rates of decline with time even when synthetic material was compared with collagen. Accordingly, these injections should be viewed as a nonpermanent treatment of SUI, with sustained continence found in only 25 percent of patients at 5 years following injection (Gorton, 1999).

One major advantage to urethral injection is its low associated risk of complications. Side effects of collagen injection generally are transient and may include vaginitis, acute cystitis, and voiding dysfunction symptoms. Of these, urinary retention for a few days after the procedure is the most common. Long-term retention, however, is not a significant risk. A more serious complication is persistent de novo urgency, which may develop in as many as 10 percent of women following injection (Corcos, 1999, 2005). In addition, allergic reaction is a possibility. Therefore, skin testing with a 0.1-mL intradermal test injection is recommended 1 month prior to the first injection (CR Bard, Inc., 2000).

ANTIBIOTIC PROPHLYAXIS

Urinary tract infection commonly can follow urethral injection. Therefore, a suitable antibiotic is administered orally after the procedure is complete.

Intraoperative

CHOICE OF BULKING AGENT

In the United States, several agents are currently available for urethral injection: autologous fat, bovine collagen, carbon-coated synthetic microspheres (Durasphere, Carbon Medical Technologies, Inc., St. Paul, MN), calcium hydroxyapatite particles (Coaptite, Boston Scientific, Natick, MA), and ethylene vinyl alcohol copolymer (Tegress, C.R. Bard, Inc., Covington, GA). The more commonly used agent in the United States is Contigen (C.R. Bard, Inc., Covington, GA), a suspension containing purified bovine collagen that has been crosslinked with glutaraldehyde.

However, because collagen lacks durability over time, other agents have been investigated as bulking agents. Autologous fat

provides limited success in the treatment of SUI owing to rapid degradation and re-absorption. For this reason, it is not employed primarily for this use (Haab, 1997; Lee, 2001). Synthetic agents also are available and effective, but long-term comparative studies with collagen are currently lacking (Chrouser, 2004; Lightner, 2002).

Surgical Steps

1. **Anesthesia and Patient Positioning.** Urethral injection for most patients can be performed in an office setting with cystoscopy capability. The patient is placed in dorsal lithotomy position, the vulva is surgically prepared, and the bladder is drained. Two-percent lidocaine jelly is instilled into the urethra 10 minutes prior to the procedure. If necessary, topical 20-percent benzocaine can be used as an analgesic on the vulva, and 4 mL of 1-percent lidocaine can be injected in divided doses at the 3 and 9 o'clock positions of the urethra.

2. **Transurethral Approach: Needle Placement.** A cystoscope is positioned within the distal urethra so that the midurethra, proximal urethra, and bladder neck are viewed simultaneously. A 22-gauge spinal needle attached to a syringe carrying the bulking agent is introduced through the cystoscopic sheath. With the bevel pointing toward the urethral lumen, the needle is directed at a 45-degree angle to the lumen and is inserted into the urethral wall at the 9 o'clock position and at the level of the midurethra.

   After the needle tip penetrates the urethral wall and the bevel is no longer seen, the needle is advanced parallel to the urethral lumen for 1 to 2 cm. This positions the needle at the level of the proximal urethra.

3. **Injection.** The bulking agent is injected under constant pressure, and the submucosal lining begins to rise (Fig. 42-6.1). The needle is withdrawn slowly to bulk the proximal and midurethra. Bulking agent is administered until coaptation of the mucosa has developed (Fig. 42-6.2). In general, one to two syringes (2.5 to 5 mL) of collagen are used per procedure. These steps then are repeated at the 3 o'clock position.

   Ideally, the number of needle holes made into the urethral wall should be minimized to avoid leakage of bulking agents through these punctures. Thus, if a second syringe of agent is required to achieve coaptation, the originally positioned needle remains in place, and a second syringe of agent is attached.

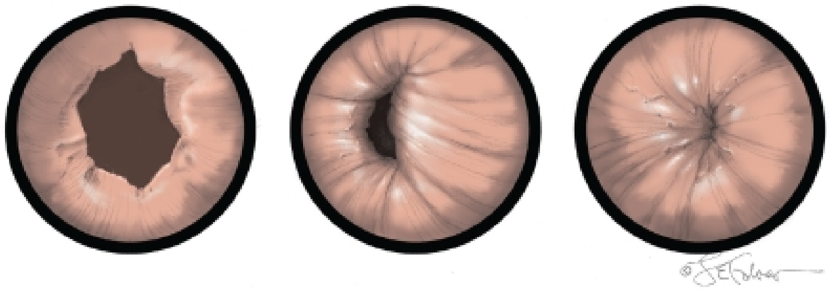
Injection of bulking agent.

FIGURE 42-6.2



Source: Schorge JO, Schaffer JI, Halvorson LM, Hoffman BL, Bradshaw KD, Cunningham FG: *Williams Gynecology*: http://www.accessmedicine.com

Corresponding cystoscopic views of urethral coaptation as bulking agent is injected, as shown in Figure 42-6.1.

4. **Cystoscope Removal.** Once coaptation of the mucosa is achieved, as the cystoscope is removed, care should be taken not to advance it proximal to the injection site. This avoids forceful compression of the deposited agent.

Postoperative

Women are discharged home following their first postinjection voiding. Oral antibiotic prophylaxis is recommended. Women should abstain from intercourse for 10 days following injection but otherwise may resume usual activities.

If urinary retention develops, then intermittent self-catheterization (ISC) is begun and continued until retention resolves. If a woman is unable to perform ISC, a temporary Foley catheter is placed. However, catheter placement potentially can compress deposited bulking agent collagen and diminish urethral coaptation.

Two weeks following injection, it is our practice to assess treatment success. If patients fail to achieve desired degrees of continence, additional injections are planned to improve urethral coaptation.

42-7 URETHROLYSIS

Uretholysis is the loosening or release of a previous urethral suspension repair. This type of release is used in women with symptoms of urethral obstruction, including urinary retention and voiding dysfunction, following suspension. It can be performed either vaginally or abdominally. A vaginal approach is used predominantly and can mobilize the urethra and bladder neck successfully. An abdominal approach, however, may afford a better opportunity to mobilize the bladder from the pubic symphysis and also may be selected in instances in which the initial surgery was performed via laparotomy.

Debate exists as to the need of a concurrent anti-incontinence procedure to compensate for urethral support lost with urethrolysis. In many cases, residual scarring prevents stress incontinence, and our belief is to avoid repeating a second potentially obstructing procedure.

Preoperative

PATIENT EVALUATION

In women with bladder neck obstruction, there is a temporal relationship between surgery and symptoms. Objective assessment with urodynamic testing is performed to determine the cause of voiding dysfunction and differentiate between a hypotonic bladder and obstruction. Obstruction may result from bladder neck obstruction or pelvic organ prolapse. Thus, a thorough examination for

prolapse should be included.

CONSENT

In addition to the usual surgical risks, bleeding may be a significant complication due to vascularity in the space of Retzius. Additionally, dissection of dense scarring around the urethra and bladder may place these structures at risk of laceration.

Patients should be counseled on potential surgical outcomes. First, because of re-formation of scar tissue, urethrolysis may fail to relieve symptoms. In contrast, postoperative incontinence may follow deconstruction of the prior anti-incontinence support.

PATIENT PREPARATION

Bowel preparation prior to urethrolysis is individualized. Antibiotic prophylaxis is administered prior to surgery to decrease risks of postoperative wound and urinary tract infection.

Intraoperative

VAGINAL APPROACH

Surgical Steps

1. **Anesthesia and Patient Positioning.** Urethrolyis may be performed under general or regional anesthesia. The patient is placed in the high lithotomy position using candy-cane stirrups. The vagina is surgically prepared, and a Foley catheter containing a 30-mL balloon is placed into the bladder.

2. **Vaginal Incision.** Traction is placed on the Foley catheter to identify the bladder neck and assess the degree of scarring. Either a vertical midline or U-shaped incision is made in the anterior vaginal wall at the level of the proximal urethra and bladder

   (Fig. 42-7.1). Sharp dissection is used to separate the vaginal epithelium from underlying tissues and is extended bilaterally toward the inferior edge of each pubic rami.

   Dissection frees the urethra by dividing scar tissue or prior sling material between the urethra and pubic rami. If prior sling material is identified, this may be incised or excised, if necessary. Bleeding is encountered frequently and can be controlled with direct pressure or vessel ligation.

   After this lateral dissection, the urogenital diaphragm is perforated, and the space of Retzius is entered (Fig. 42-7.2). Careful blunt dissection within this space and at the back of the symphysis pubic additionally will assist in mobilizing the proximal urethra.

FIGURE 42-7.1

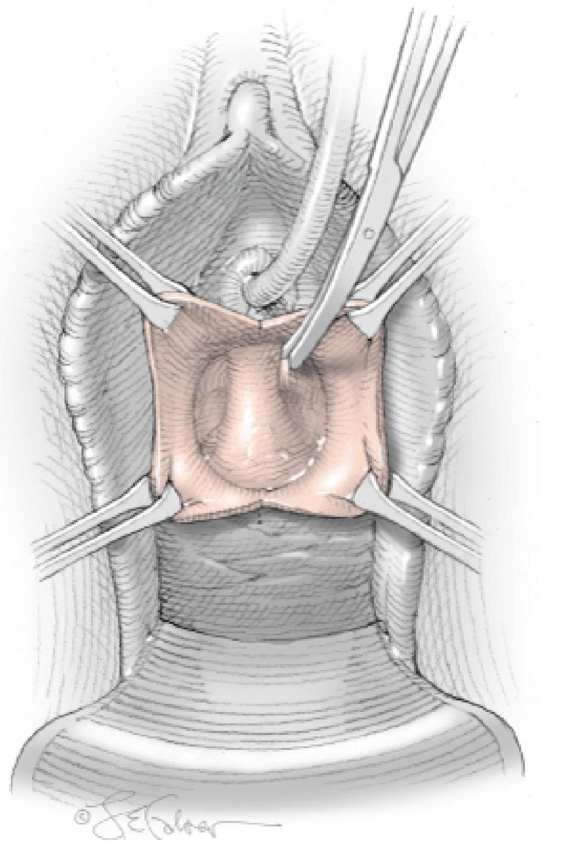
Vaginal incision.

FIGURE 42-7.2



Source: Schorge JO, Schaffer JI, Halvorson LM, Hoffman BL, Bradshaw KD, Cunningham FG: *Williams Gynecology*: http://www.accessmedicine.com

Urethral dissection.

3. **Incision Closure.** Following adequate mobilization of the urethra, the vaginal incision is reapproximated with a running closure using 2-0 delayed-absorbable suture.

ABDOMINAL APPROACH

Surgical Steps

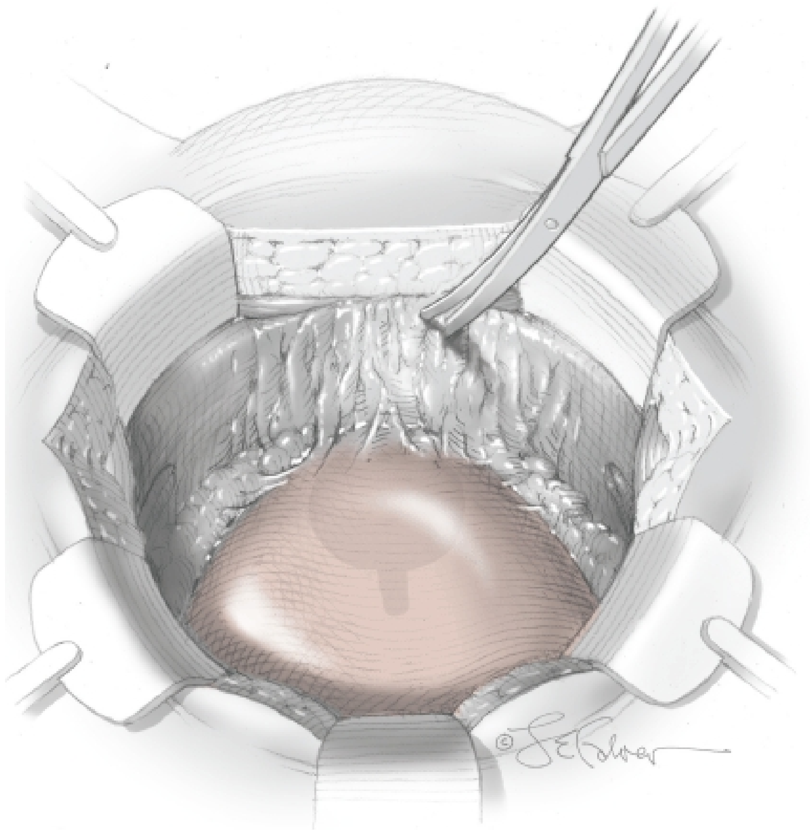
1. **Anesthesia and Patient Positioning.** As with a vaginal approach, urethrolyis may be completed under general or regional anesthesia. For an abdominal approach, Allen stirrups and standard lithotomy positioning are preferred. This allows vaginal access to the surgeon's hand during dissection. The abdomen and vagina are surgically prepared, and a Foley catheter containing a 30-mL balloon is placed within the bladder.

2. **Abdominal Incision.** A low transverse incision typically is preferred for this procedure to permit easy access to the space of Retzius. Either a Pfannenstiel or a Cherney incision usually is selected (see Sections 41-2, Pfannenstiel Incision and 41-3, Cherney Incision).

3. **Entry into the Space of Retzius.** The correct plane of dissection to enter the space of Retzius lies directly behind the pubic bone. Loose areolar tissue is gently dissected downward in a mediolateral fashion with fingers or sponge beginning immediately behind the pubic bone. If the correct plane is entered, this potential space opens easily. However, women requiring urethrolysis typically have had prior surgery within this space. As a result, tissue may be densely adhered, and

sharp downward dissection along the posterior surface of the symphysis may be needed to enter this space (Fig. 42-7.3).

FIGURE 42-7.3



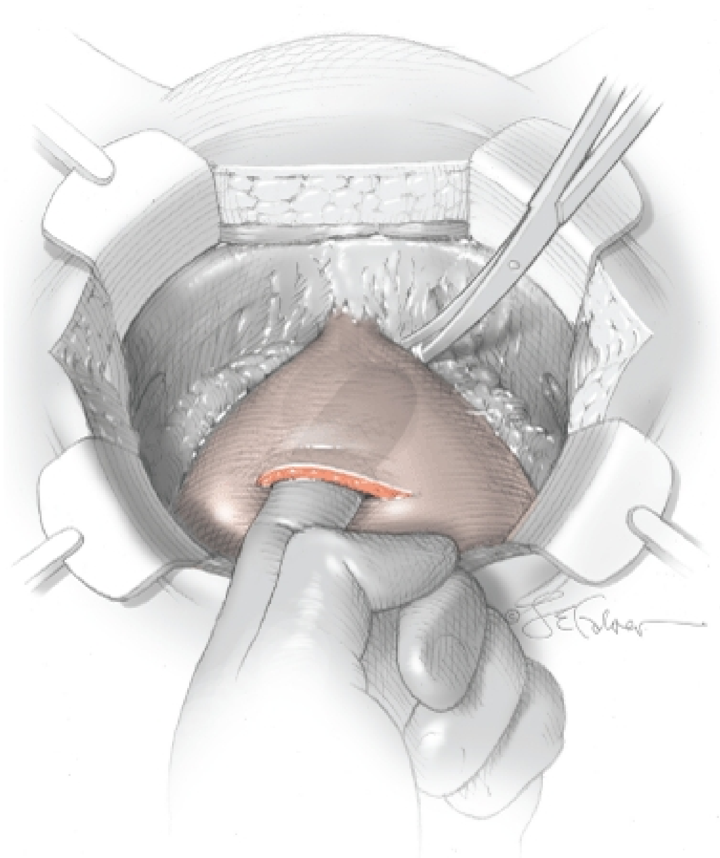
Source: Schorge JO, Schaffer JI, Halvorson LM, Hoffman BL, Bradshaw KD, Cunningham FG: *Williams Gynecology*: http://www.accessmedicine.com

Dissection in the space of Retzius.

4. **Bladder Dissection and Urethrolysis.** The bladder also typically is densely adhered to the back of the symphysis. Sharp dissection with the curved surface of scissors facing the symphysis is directed against the symphysis. This technique minimizes the risk of bladder laceration. At times, however, an intentional cystotomy may be required so that a finger can be placed inside the bladder to aid dissection (Fig. 42-7.4).

   Sharp dissection is continued inferiorly and laterally down the inner surface of the symphysis to free the bladder and eventually also the proximal urethra. Bleeding is common during dissection and may be controlled with sutures or clips.

FIGURE 42-7.4



Source: Schorge JO, Schaffer JI, Halvorson LM, Hoffman BL, Bradshaw KD, Cunningham FG: *Williams Gynecology*: http://www.accessmedicine.com

Intentional cystotomy to aid bladder and urethral dissection.

5. **Abdominal Closure.** The abdomen is closed in a standard fashion (see Section 41-2, Pfannenstiel Incision).

Postoperative

An active bladder test is performed following catheter removal. If large residual volumes are found, intermittent self-catheterization or replacement of the catheter is required. If cystotomy was performed, the duration of catheterization depends on cystotomy size but typically is continued for several weeks.

42-8 MIDURETHRAL SLING RELEASE

Symptoms of obstruction may develop following urethral sling procedures, specifically tension-free vaginal tape (TVT) and transobturator tape sling (TOT) procedures. This complication develops in 4 to 6 percent of patients after TVT and generally is identified days to weeks after surgery. When obstruction is diagnosed, surgical release is indicated and involves simple cutting of the sling material.

Preoperative

PATIENT EVALUATION

Inability to fully empty the bladder may be due to urethral obstruction or a hypotonic bladder. New-onset urinary retention after a midurethral sling procedure (TVT or TOT) usually is due to sling tightness. However, there may be other factors involved, such as pre-existing or de novo bladder hypotonia. Therefore, prior to TVT urethrolysis, it is prudent to perform urodynamic testing to prove that symptoms are due to obstruction rather than to bladder hypotonia. Additionally, tape may erode into the bladder or urethra in cases of obstruction, and cystoscopy allows exclusion of this complication.

CONSENT

Associated with midurethral sling release, the risks of incontinence recurrence and intraoperative bladder or urethral injury should be considered in the consenting process.

PATIENT PREPARATION

This is a minor surgical procedure, and no specific patient preparation is required.

Intraoperative

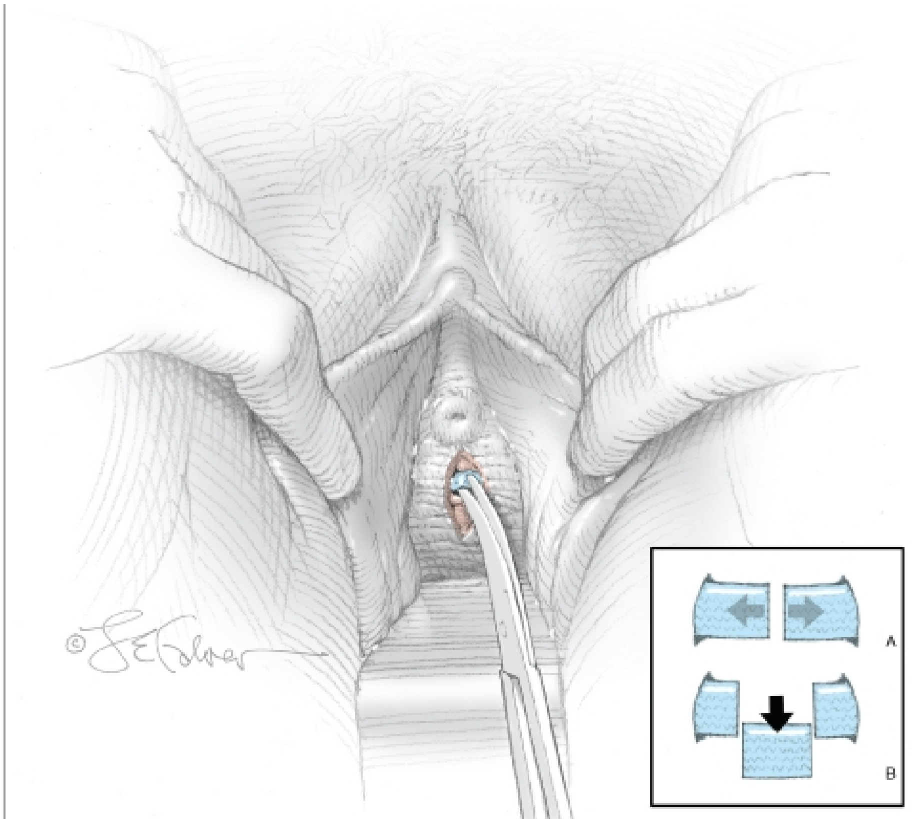
Surgical Steps

1. **Anesthesia and Patient Positioning.** This surgery can be performed with local, regional, or general anesthesia as an outpatient procedure. A patient is placed in high lithotomy position using candy-cane or Allen stirrups. The vagina is surgically prepared, and a Foley catheter is placed.

2. **Vaginal Incision and Tape Identification.** A midline suburethral incision that follows the prior primary surgical incision is made sharply. Careful dissection is used to expose the sling material and to define the urethral borders.

   Often because of increased sling tension, sling material is stretched and measures only half of its expected width. Additionally, there is usually extensive tissue ingrowth into the sling material, and identification and mobilization can be difficult (Fig. 42-8.1). Occasionally, a sling may migrate to the proximal urethra, and in these instances, the vaginal incision may require cephalad extension.

FIGURE 42-8.1



Mesh transection through vaginal incision. **A.** Mesh and retraction. **B.** Mesh excision.

3. **Incision of Sling Material.** After mobilization of the material, a hemostat is opened between the sling and urethra. Metzenbaum scissors are used to cut the sling material. In general, incision leads to immediate retraction of sling ends (Fig. 42-8.1A). If retraction does not follow, a 1-cm segment of material should then be excised (Fig 42-8.1B).

4. **Incision Closure.** After vigorous irrigation, the vaginal epithelium is closed in a continuous running fashion using 2-0 delayed-absorbable suture.

Postoperative

Prior to discharge, an active voiding trial is performed. If a Foley catheter remains, a second voiding trial can be repeated in a few days or at the surgeon's discretion. If a woman is performing self-catheterization, this is continued until postvoid residuals fall below 100 mL.

42-9 URETHRAL DIVERTICULUM REPAIR

The approach to urethral diverticulum repair varies and depends on the location, size, and configuration of the diverticular sac (see Chap. 26, Classification). For those that are near the bladder neck, partial ablation often is selected to avoid damage to the bladder neck and continence mechanism. For midurethral diverticulum, simple diverticulectomy typically is indicated. For those located at the urethral meatus, the Spence procedure may be warranted. With this technique, a distal diverticulum and urethral meatus are opened sharply together to form a large single meatus. Finally, for those with a complex diverticulum that may surround the urethra, a combination of techniques may be necessary.

Preoperative

PATIENT EVALUATION

Accurate information regarding diverticular anatomy is essential to surgical planning and patient counseling. For this, magnetic resonance (MR) imaging is a superior radiographic study to delineate diverticular configuration (see Fig. 26-6). Additionally, cystoscopy is valuable in locating sac openings along the urethral length.

CONSENT

With diverticular repair, damage to urethral continence mechanisms may lead to postoperative incontinence. Alternatively, urethral stricture or stenosis or urinary retention may develop depending on the extent and location of surgery. Additionally, urethrovaginal fistula and bladder injury may result. If a Spence procedure is selected, urethral meatus anatomy typically is altered, and a spraying pattern may result with urination.

PATIENT PREPARATION

To prevent wound infection, intravenous antibiotic prophylaxis is administered immediately prior to surgery (see Chap 39, Surgical Site Infection Prophylaxis). It is our practice at the University of Texas Southwestern Medical Center to recommend bowel preparation prior to diverticular repair to decompress the rectosigmoid, although this practice is not mandatory.

Intraoperative

DIVERTICULECTOMY

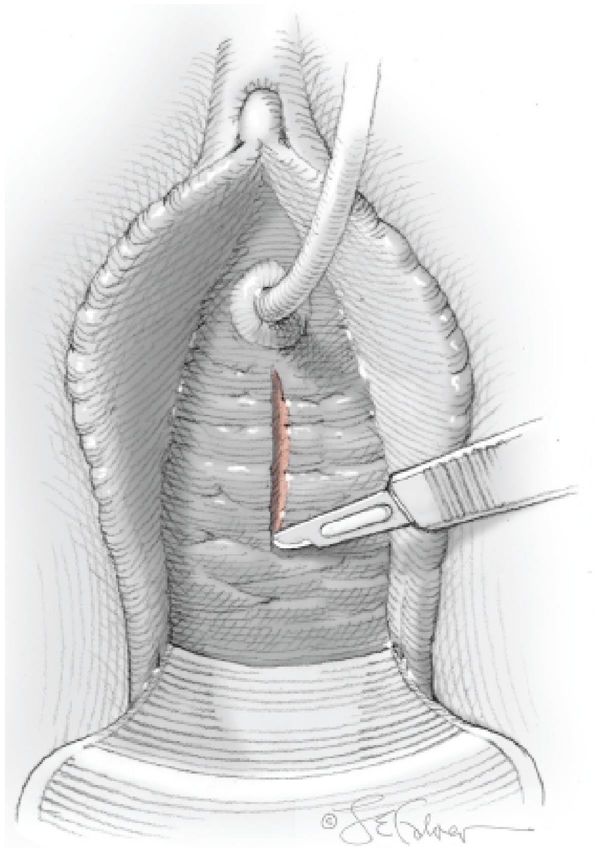
Surgical Steps

1. **Anesthesia and Patient Positioning.** Diverticulum excision typically is performed as an inpatient procedure under general or regional anesthesia. The patient is placed in high lithotomy position in candy-cane stirrups to provide maximal surgical exposure. The vagina is surgically prepared, and a Foley catheter containing a 10-mL balloon is placed in the bladder to assist in identifying the bladder neck.

2. **Cystourethroscopy.** This procedure is performed at the onset to locate the diverticular opening and exclude other abnormalities.

3. **Vaginal Incision.** A midline incision is made on the anterior vaginal wall over the diverticulum, and the vaginal epithelium is dissected sharply off the fibromuscular layer of the vaginal wall (Fig. 42-9.1). Ample epithelium is freed to allow adequate exposure and to permit tissue approximation without excess tension.

FIGURE 42-9.1



Source: Schorge JO, Schaffer JI, Halvorson LM, Hoffman BL, Bradshaw KD, Cunningham FG: *Williams Gynecology*: http://www.accessmedicine.com

Vaginal incision.

4. **Diverticulum Exposure.** A longitudinal incision is made through the fibromuscular layer to reach the diverticular sac. Sharp dissection then is used to completely mobilize and expose the diverticular sac and neck (Fig. 42-9.2). During dissection, the sac may be entered inadvertently or intentionally (Fig. 42-9.3). If this happens, the diverticular walls are grasped with Allis clamps, and dissection is continued. Caution and awareness of the location of the urethra are essential to avoid damage.

FIGURE 42-9.2

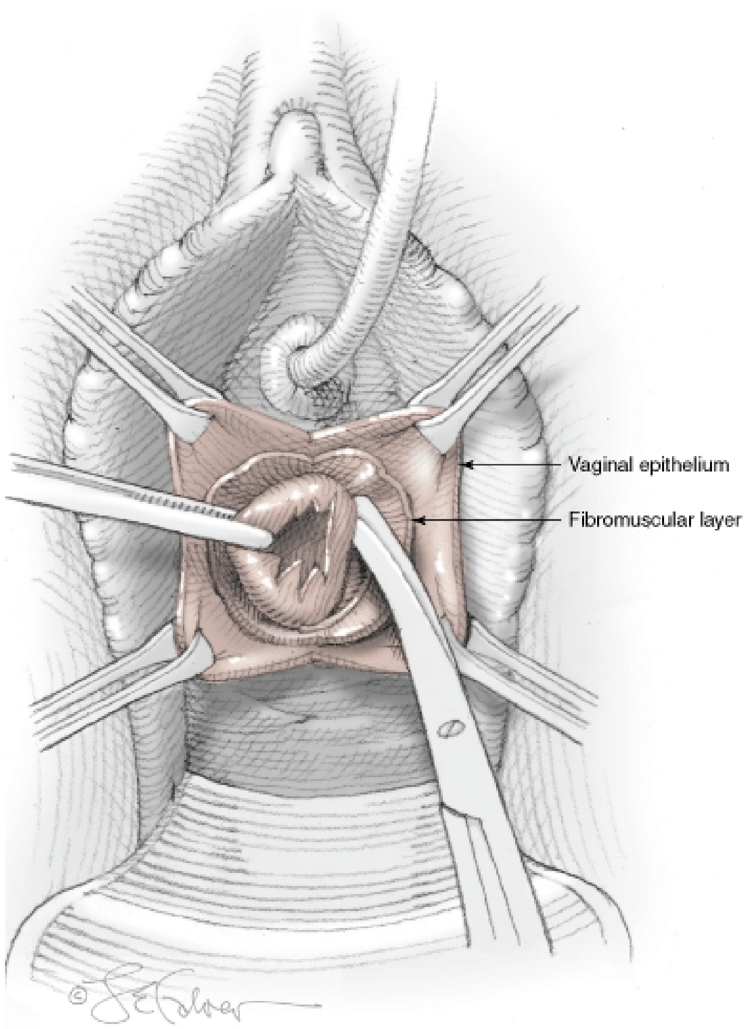
Diverticular sac dissection.

FIGURE 42-9.3



Source: Schorge JO, Schaffer JI, Halvorson LM, Hoffman BL, Bradshaw KD, Cunningham FG: *Williams Gynecology*: http://www.accessmedicine.com

Diverticulum excision.

5. **Diverticulum Excision.** At its neck, the diverticulum is excised from the urethra.

6. **Urethral Closure.** The urethral incision defect is closed with interrupted 4-0 delayed-absorbable sutures over the Foley catheter (Fig. 42-9.4). Fibromuscular layers are re-approximated off tension in two or more layers in a vest-over-pants fashion with 2-0 delayed-absorbable suture (Fig. 42-9.5). Redundant vaginal epithelium is trimmed, and the epithelium is closed in a running fashion with 2-0 delayed-absorbable suture.

Fibromuscular layer reapproximation.

PARTIAL DIVERTICULAR ABLATION

Surgical Steps

1. **Vaginal Incision.** A midline incision is made on the anterior vaginal wall over the diverticulum, and the vaginal epithelium is dissected sharply off the fibromuscular layer of the vaginal wall. Ample epithelium is freed to allow adequate exposure and later to permit defect closure off tension. The Foley catheter and balloon can be placed on gentle tension to aid in identifying the bladder and bladder neck to avoid injury.

2. **Diverticulum Exposure.** A longitudinal incision is made through the fibromuscular layer to the diverticular sac. Sharp dissection is used to completely mobilize and expose the sac. The diverticulum is opened, and the communication with the urethra is identified. To avoid injury to the proximal urethra and bladder neck, the diverticular sac, but not the neck of the diverticulum, is excised sharply. As much of the sac that can be accessed is removed.

3. **Sac Closure.** The base of the sac then is sutured side to side with 2-0 delayed-absorbable suture to cover the urethral defect. A second, and possibly a third, imbricating layer using the vaginal muscularis is created with similar suture. Excess vaginal epithelium that had previously covered the diverticulum is excised. The vaginal epithelium is closed in a running fashion with a 2-0 delayed-absorbable suture.

SPENCE MARSUPIALIZATION

Surgical Steps

1. **Meatal Incision.** Tips of Metzenbaum scissors are inserted into the urethral meatus and vagina. An incision is made through

the posterior urethral wall and entire thickness of the diverticulum and includes the distal anterior vaginal wall.

2. **Marsupialization.** A circumferential running pattern using 4-0 delayed-absorbable suture is used around the enlarged meatus to re-approximate cut edges of the vaginal and urethral epithelia.

Postoperative

Catheter management is the most important aspect of postoperative care. Although no consensus guidelines exist, most experts recommend catheter placement for 5 to 7 days. Surgeries of increasing complexity may require longer catheter duration.

42-10 VESICOVAGINAL FISTULA: LATZKO TECHNIQUE

Vesicovaginal fistulas may be repaired either vaginally or abdominally (see Chap. 26, Route of Surgical Repair). A vaginal approach is preferred for most fistulas seen in the United States, which are posthysterectomy apical fistulas. This approach is selected because of its comparable success rates, lower morbidity, and faster patient recovery. The most commonly performed vaginal procedure is the Latzko technique, which is a partial colpocleisis that obliterates the upper vagina for 2 to 3 cm around the fistula. However, an abdominal approach may be necessary for patients in whom a fistula cannot be accessed vaginally or in whom prior vaginal repairs have been unsuccessful. With the abdominal approach, omentum or peritoneum can be mobilized and interposed between the bladder and vagina to prevent recurrence.

Principles of fistula repair dictate that a repair must be performed in noninfected and noninflamed tissues. A second principle states that tissues should be approximated without excess tension. If these guidelines are followed, success rates typically are good and range from 67 to 100 percent. In the United States, most fistulas follow hysterectomy for benign causes, and these fistulas are associated with high cure rates.

Fistulas associated with gynecologic cancer and radiation therapy, however, may require adjunctive surgical procedures such as vascular flaps because these defects develop in poorly vascularized or fibrotic tissue. Even with these measures, success rates are lower.

Preoperative

PATIENT EVALUATION

Prior to repair, a fistula should be well characterized. Complex fistulas with multiple tracts or a ureterovaginal fistula should be identified. For this, proper evaluation should include intravenous pyelography (IVP) and cystoscopy (see Fig. 26-1). Ureterovaginal fistulas usually are associated with upper tract abnormalities such as hydroureter and hydronephrosis. Therefore, normal IVP findings should reassure the surgeon that ureteral involvement is absent. Additionally, this testing enables the surgeon to identify the proximity of ureters relative to a fistula for surgical planning. In general, routine posthysterectomy vesicovaginal fistulas develop at the vaginal apex. This is well away from the ureters, which enter the bladder at the level of the midvagina.

Whether or not surgery can be performed vaginally depends on the ability to obtain adequate exposure of a fistula. Therefore, during physical examination, the surgeon must assess if a fistula can be brought down into the surgical field and if a patient's pelvis affords adequate space for vaginal surgery. Some degree of prolapse of the vaginal apex is helpful for a vaginal approach to fistula repair.

Additionally, tissue infection or inflammation should be excluded. If these are identified, fistula repair should be delayed until resolution. If a fistula is recognized within a few days following hysterectomy, it may be repaired immediately, prior to a brisk inflammatory response. However, if surgical repair is not undertaken within a few days following the initial surgery, then a delay of 4 to 6 weeks is recommended to decrease tissue inflammation.

CONSENT

There is a significant recurrence rate with fistula repair, and patients should be aware that initial surgery may not be curative. With the Latzko procedure, the vagina is moderately shortened in most cases. Therefore, the risk of postoperative dyspareunia should be

included in the consent.

PATIENT PREPARATION

Bowel preparation is administered the evening prior to surgery. This decompresses the rectosigmoid and minimizes fecal contamination of the surgical field. Immediately prior to surgery, intravenous antibiotic prophylaxis commonly is administered to decrease postoperative wound infection risks.

Intraoperative

LATZKO VAGINAL REPAIR

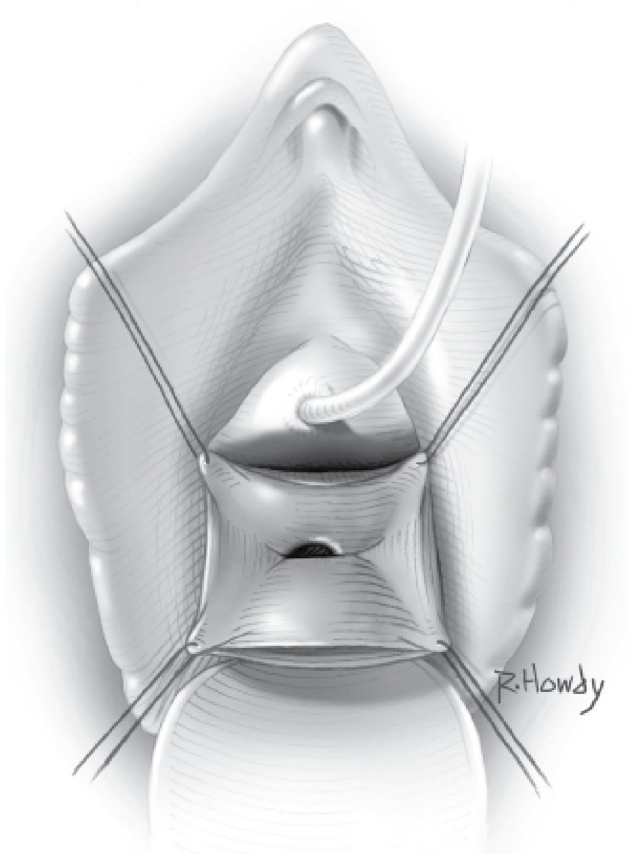
Surgical Steps

1. **Anesthesia and Patient Positioning.** In most cases, repair is performed under general or regional anesthesia, and the need for postoperative hospitalization is individualized. The patient is placed in dorsal lithotomy position, and the vagina is surgically prepared. If ureters lie close to a fistula, ureteral stents should be placed (see Section 42-1, Diagnostic and Operative Cystoscopy and Urethroscopy). Cystoscopy is required during the procedure to document ureteral patency and assess bladder integrity.

2. **Delineating a Fistulous Tract.** The course of a fistulous tract must be identified. If the tract is large enough to accept a pediatric Foley catheter, the tube is threaded through the fistulous opening, and the balloon is inflated within the bladder. If a tract cannot be delineated this manner, then lacrimal duct probes or other suitable narrow dilators should be used to trace the tract course and direction. Subsequently, attempts should be made to dilate the tract and place a pediatric catheter.

3. **Exposure.** The fistula must be brought into the operative field. If catheterization of a fistulous tract is possible, tension on the catheter will allow this. Alternatively, four sutures can be placed in the vaginal wall surrounding a fistula and used to pull the fistula into the operative field (Fig. 42-10.1). Some advocate performing a mediolateral episiotomy to gain exposure, although this is not our practice.

FIGURE 42-10.1

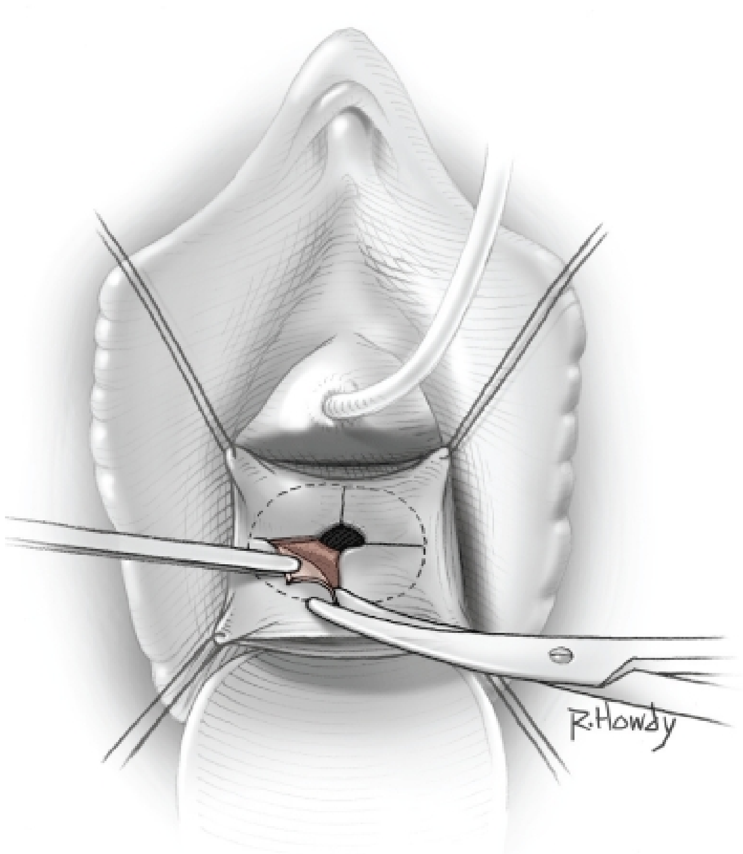


Source: Schorge JO, Schaffer JI, Halvorson LM, Hoffman BL, Bradshaw KD, Cunningham FG: *Williams Gynecology*: http://www.accessmedicine.com

Stay sutures in the vaginal wall improve fistula access.

4. **Vaginal Incision.** A vaginal incision is made circumferentially approximately 1 cm around the fistulous tract (Fig. 42-10.2). Vaginal mucosa surrounding the tract then is mobilized sharply and excised using Metzenbaum scissors.

FIGURE 42-10.2



Source: Schorge JO, Schaffer JI, Halvorson LM, Hoffman BL, Bradshaw KD, Cunningham FG: *Williams Gynecology*: http://www.accessmedicine.com

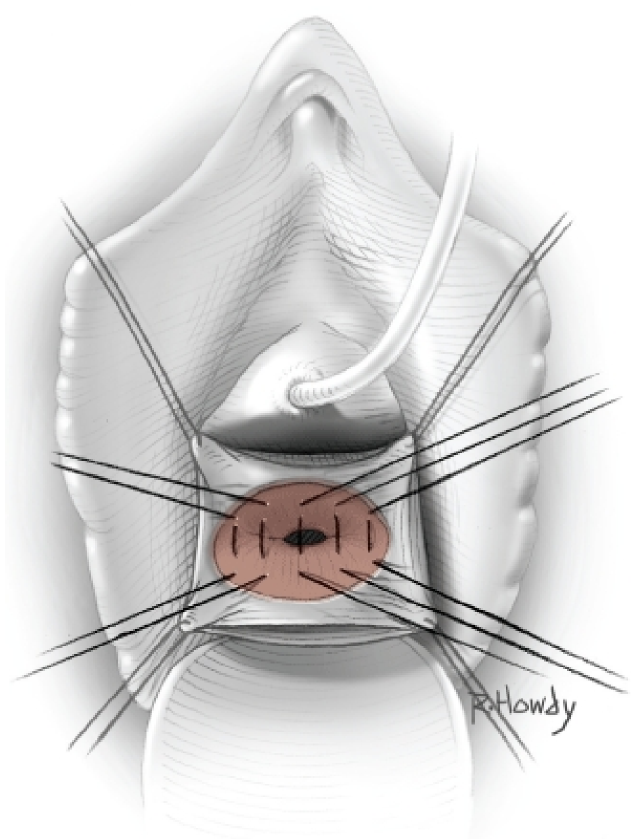
Vaginal incision.

5. **Tract Excision.** The fistula tract may or may not be excised. If the tract is excised, surgeons should be aware that a larger defect for repair will result. However, in situations in which a tract is indurated, excision is warranted.

6. **Fistula Closure.** If the tract is excised, the bladder mucosa is re-approximated with 3-0 delayed-absorbable sutures. Subsequently, anterior and posterior edges of the vaginal fibromuscular layers are approximated over this repair with interrupted stitches of 3-0 delayed-absorbable sutures (Fig. 42-10.3). After the first suture line is placed through the fibromuscular layer, a second and possibly a third line are created on top of the first (Fig. 42-10.4). Following this closure, the bladder should be filled with 100 mL of fluid to document a watertight repair. If it is not watertight, additional reinforcing sutures can be placed.

   After fibromuscular layers of the vaginal wall are closed, the epithelium is closed in a continuous running fashion using 3-0 delayed-absorbable suture.

FIGURE 42-10.3



Source: Schorge JO, Schaffer JI, Halvorson LM, Hoffman BL, Bradshaw KD, Cunningham FG: *Williams Gynecology*: http://www.accessmedicine.com

Second fibromuscular layer closure over fistula and vaginal epithelium re-approximation.

7. **Cystoscopy.** Cystoscopy is performed to document ureteral patency and to inspect the incision site.

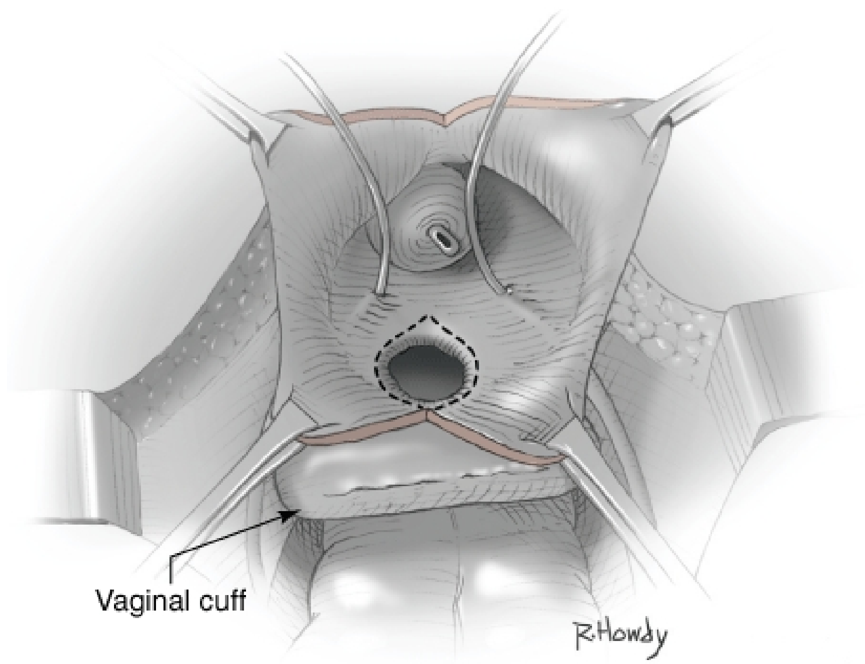
ABDOMINAL REPAIR

Surgical Steps

1. **Anesthesia and Patient Positioning.** In most cases, abdominal repair is performed under general anesthesia. The patient is placed in low lithotomy position with the use of Allen stirrups. With the patient's thighs parallel to the ground and the legs separated, access to the vagina is maximized. The abdomen and vagina are surgically prepared.

2. **Abdominal Incision and Entry into the Bladder.** A transverse or midline abdominal entry incision can be used. If mobilization of the omentum is anticipated, a midline incision may give easier access to the omentum. A Maylard or Cherney incision alternatively may be selected. After the peritoneum is entered and the upper abdomen is explored, the bowel is packed from the operating field, and a self-retaining abdominal wall retractor is placed. The space of Retzius is opened using the technique described in Section 42-2, Burch Colposuspension, and a vertical extraperitoneal incision is made in the bladder dome (Fig. 42-10.5). Correct incision placement is aided by pulling the Foley balloon to the dome or by filling the bladder with fluid.

FIGURE 42-10.5



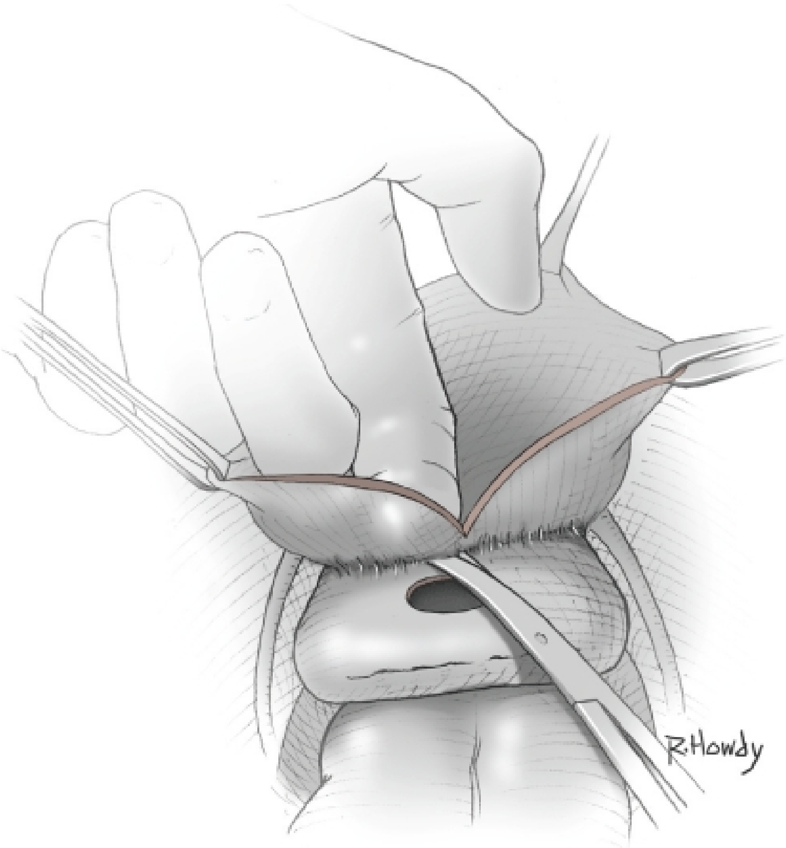
Source: Schorge JO, Schaffer JI, Halvorson LM, Hoffman BL, Bradshaw KD, Cunningham FG: *Williams Gynecology*: http://www.accessmedicine.com

Bladder incision.

3. **Delineation and Excision of the Fistulous Tract.** The fistula and ureteral orifices are visualized from within the bladder. If the fistula tract is near the orifices, ureteral stents are placed. The incision then is extended over the top and back of the bladder to the fistula tract. A lacrimal probe or catheter may be placed into the fistula tract to delineate its course. The tract then is excised.

4. **Separation of the Bladder and Vagina.** Sharp dissection is used to dissect the vagina away from the bladder in the area of the fistula (Fig. 42-10.6). Scarring may be extensive, and sharp rather than blunt dissection should be used. To aid dissection, an EEA sizer may be placed in the vagina for manipulation. The vagina should be separated widely from the bladder to allow omentum placement between the two organs.

FIGURE 42-10.6

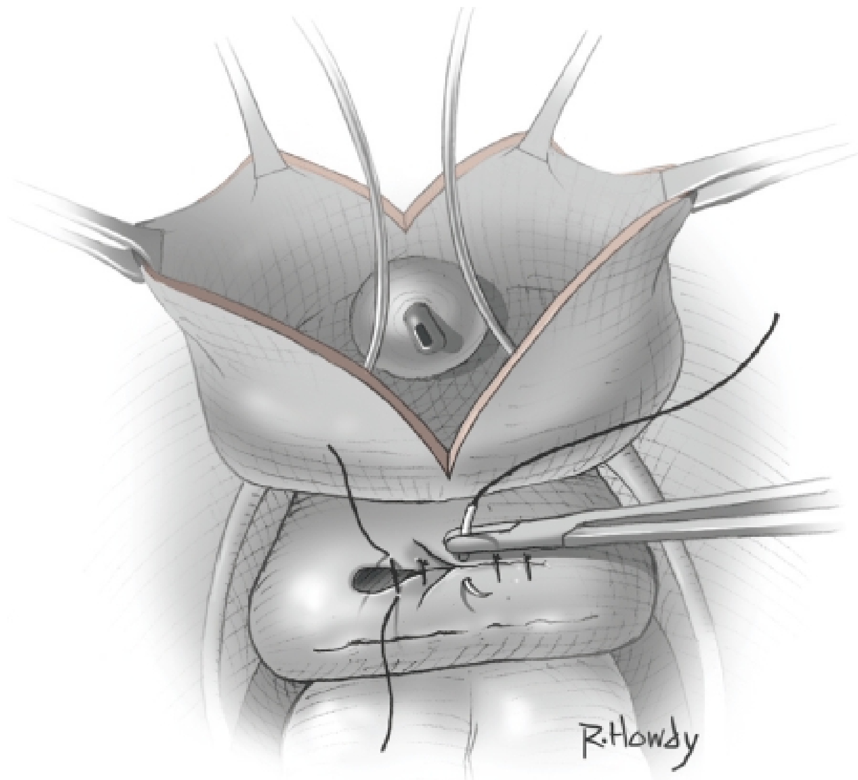


Source: Schorge JO, Schaffer JI, Halvorson LM, Hoffman BL, Bradshaw KD, Cunningham FG: *Williams Gynecology*: http://www.accessmedicine.com

Separation of the bladder and vagina.

5. **Vaginal Closure.** The vagina is closed in two layers with 2-0 delayed-absorbable suture (Fig. 42-10.7). The end-to-end anastomosis (EEA) sizer or digital manipulation of the vagina will assist this closure (see Fig. 42-17.5).

FIGURE 42-10.7



Source: Schorge JO, Schaffer JI, Halvorson LM, Hoffman BL, Bradshaw KD, Cunningham FG: *Williams Gynecology*: http://www.accessmedicine.com

Vaginal closure.

6. **Bladder Closure.** The bladder is closed in two layers using running sutures of 3-0 absorbable suture (Fig. 42-10.8). The second layer should be imbricated such that the first suture line is covered and tension is released (Fig. 42-10.9).

FIGURE 42-10.8

Second layer bladder closure.

7. **Omental or Peritoneal Interposition.** The omentum is mobilized and sutured to the anterior wall of the vagina to cover the incision line (Fig. 42-10.10). This provides a tissue layer between vagina and bladder, increases vascular flow to the area, and may improve tissue healing. Alternatively, if the omentum cannot be mobilized, peritoneum may be interposed between the bladder and vagina (Fig. 42-10.11).

FIGURE 42-10.10

Peritoneal interposition.

8. **Cystoscopy.** Cystoscopy is performed to document ureteral patency and to inspect the incision site.

9. **Incision Closure.** The abdominal incision is closed as described in Sections 41-1, Midline Vertical Incision or 41-2, Pfannenstiel Incision.

Postoperative

The bladder should be drained postoperatively to prevent overdistention and suture disruption. Transurethral and suprapubic catheter placement will ensure adequate drainage in the immediate postoperative period. At our institution, we generally continue catheterization for at least 3 weeks following vesicovaginal fistula repair.

42-11 MARTIUS BULBOCAVERNOSUS FAT PAD FLAP

The Martius bulbocavernosus fat pad flap is a vascular graft. It is used commonly in complex rectovaginal or vesicovaginal fistula repairs complicated by avascular or fibrotic tissue. Specifically, previously irradiated vaginal tissues often require this graft.

During graft placement, the bulbocavernosus fat pad is first mobilized and subsequently brought to the fistula site through a vaginal incision. By means of this graft, fistula repair layers receive additional vascular support to increase rates of successful wound healing.

Preoperative

PATIENT EVALUATION

In most instances, graft placement is anticipated for those with prior radiation or with fistula recurrence. Therefore, preoperative planning includes assessment of tissue vascularity, connective tissue strength, and ability to mobilize vaginal tissues adequately to create a multilayered fistula closure. To undergo this procedure, a woman must have adequate labial fat, and this should be assessed prior to surgery.

CONSENT

The consenting process for this procedure includes that for the primary fistula repair. Additionally, women are informed of the potential for postoperative vulvar dysesthesia, pain, or hematoma.

PATIENT PREPARATION

Preoperative bowel preparation is indicated prior to use of a Martius flap to repair rectovaginal fistulas. Preparation protocols vary according to surgeon preference and may include administration of oral cathartic solutions, laxatives, or enemas (see Table 39-10). Because of the risk of poor wound healing in these complicated fistulas, antibiotic prophylaxis with a first- or second-generation cephalosporin is warranted (see Table 39-7).

Intraoperative

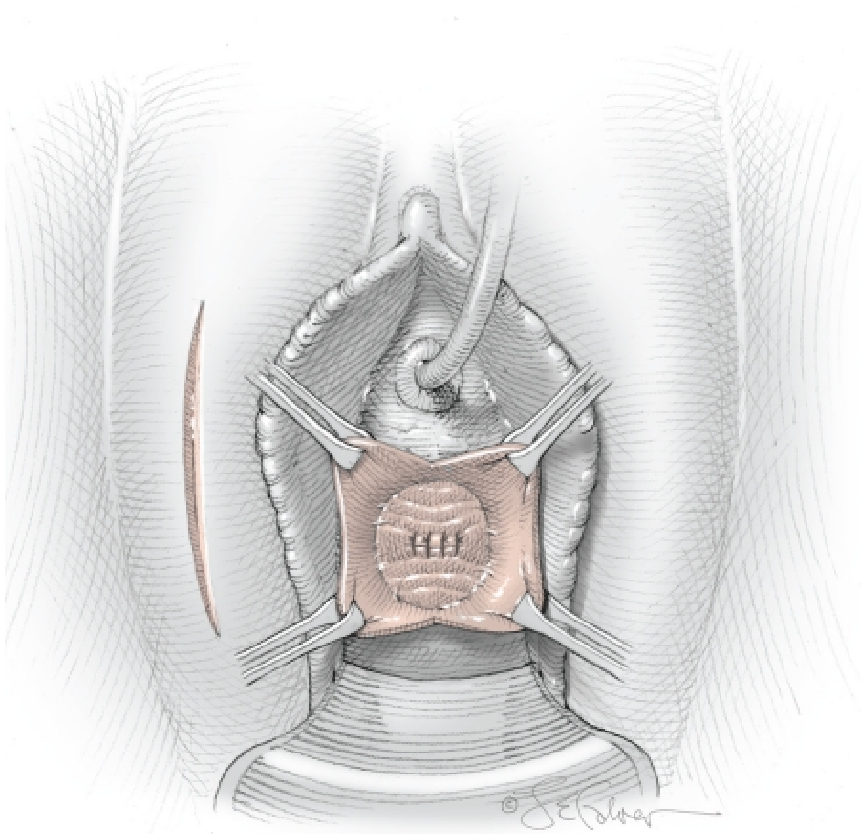
Surgical Steps

1. **Anesthesia and Patient Positioning.** In most cases, a Martius flap graft and fistula repair can be performed with general or regional anesthesia, and the need for postoperative hospitalization typically is individualized. The patient is positioned in high lithotomy position, the vagina is surgically prepared, and a Foley catheter is placed.

2. **Fistula Repair.** Rectovaginal or vesicovaginal fistulas are repaired as outlined in Sections 42-10, Vesicovaginal Fistula: Latzko Technique and 42-26, Rectovaginal Fistula Repair.

3. **Labial Incision.** After completion of fistula repair, the lateral margin of one labia majora is incised (Fig. 42-11.1). The length of the incision is tailored to specific labial anatomy and size of the graft needed. In many cases, a 6- to 8-cm incision is made below the level of the clitoris and is extended inferiorly.

FIGURE 42-11.1

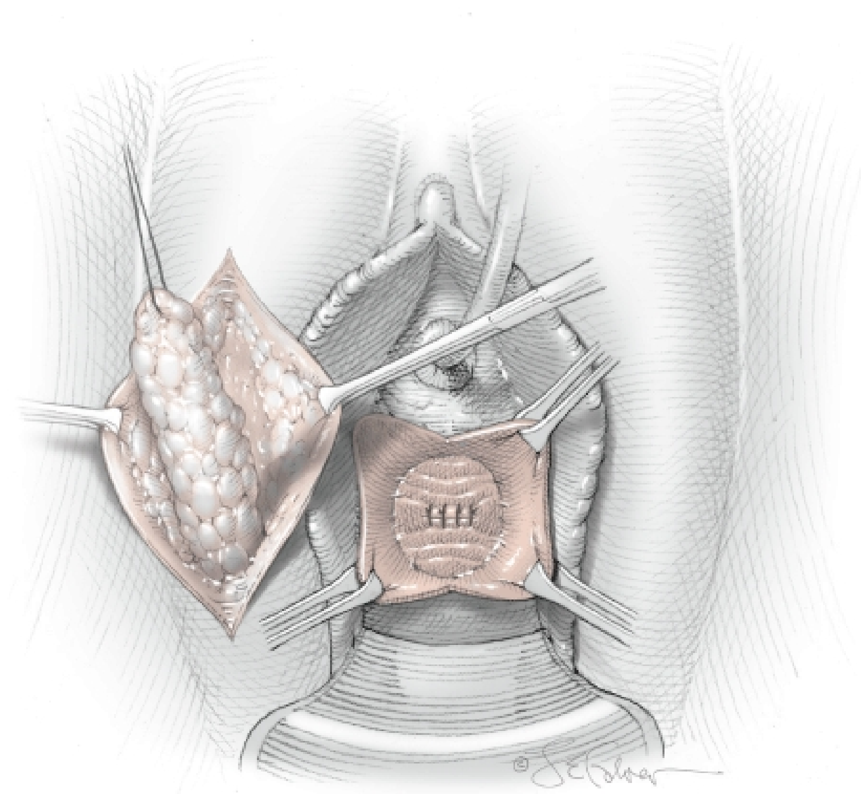


Source: Schorge JO, Schaffer JI, Halvorson LM, Hoffman BL, Bradshaw KD, Cunningham FG: *Williams Gynecology*: http://www.accessmedicine.com

Labial incision.

4. **Mobilization of the Fat Pad.** Incision edges are retracted laterally, and sharp dissection is used to mobilize the bulbocavernosus fat pad (Fig. 42-11.2). This tissue is vascular, and vessels ideally are ligated prior to transection. A broad base is left inferiorly, and the fat pad is detached superiorly.

FIGURE 42-11.2

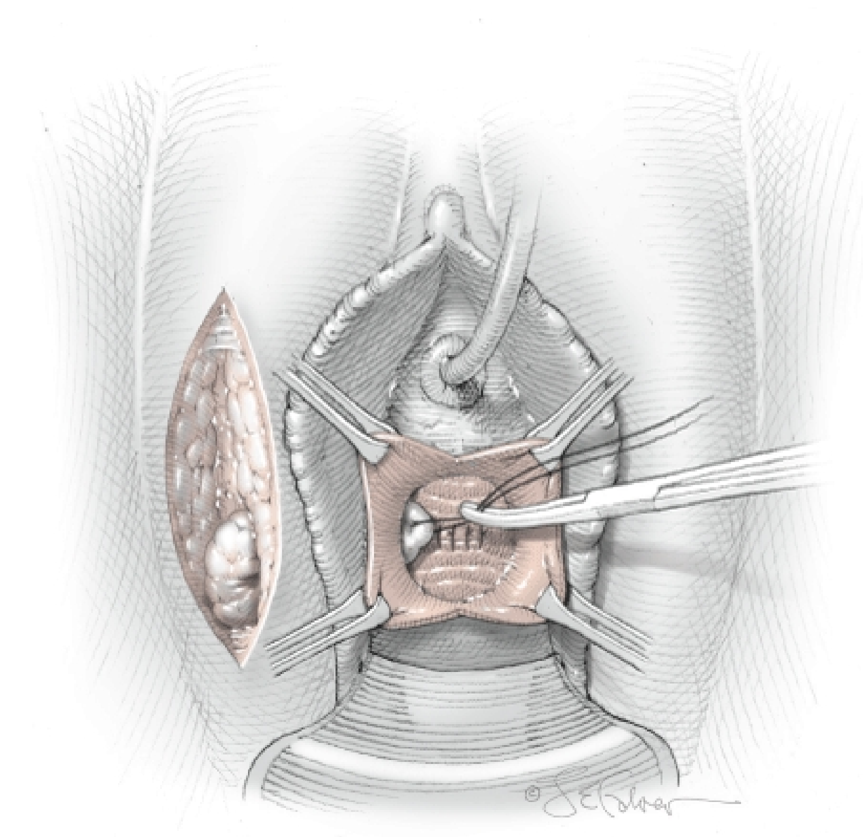


Source: Schorge JO, Schaffer JI, Halvorson LM, Hoffman BL, Bradshaw KD, Cunningham FG: *Williams Gynecology*: http://www.accessmedicine.com

Mobilization of the fat pad.

5. **Graft Placement.** After mobilization, a tunnel is created by bluntly dissecting with a hemostat from the vulvar incision underneath the vaginal epithelium to the fistula site. The tunnel must be of sufficient breadth to avoid vascular compression and resulting graft necrosis. A suture is placed at the graft tip and is used to pass the graft through the tunnel and into the vagina (Fig. 42-11.3).

FIGURE 42-11.3

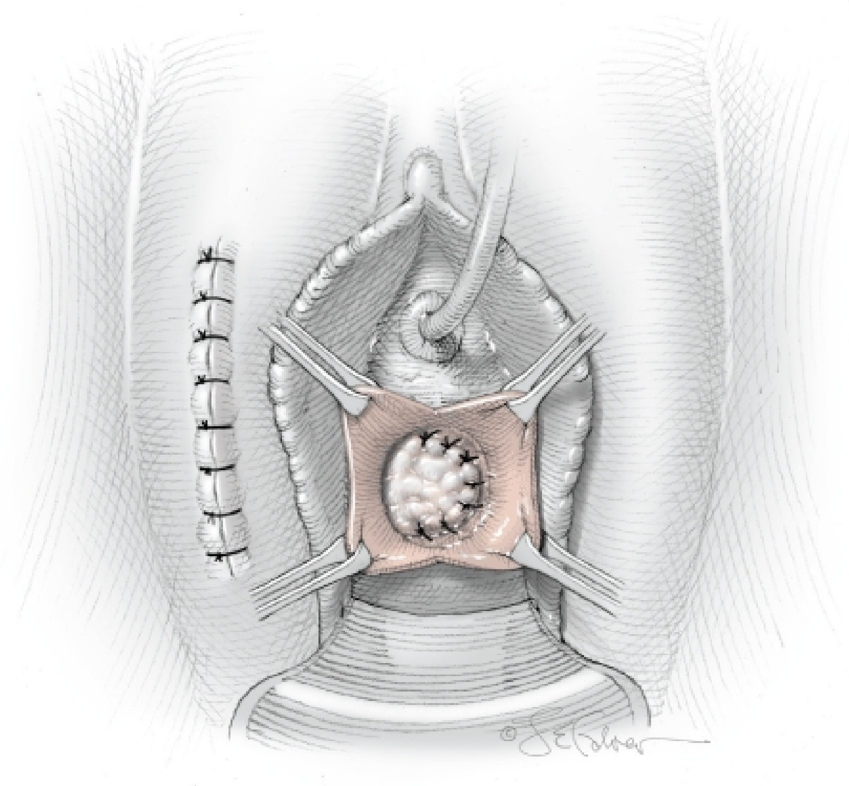


Source: Schorge JO, Schaffer JI, Halvorson LM, Hoffman BL, Bradshaw KD, Cunningham FG: *Williams Gynecology*: http://www.accessmedicine.com

Graft placement.

6. **Graft Fixation.** The graft is secured to the vaginal muscularis overlying the fistula repair with several interrupted stitches using 3-0 delayed-absorbable suture (Fig. 42-11.4).

FIGURE 42-11.4



Source: Schorge JO, Schaffer JI, Halvorson LM, Hoffman BL, Bradshaw KD, Cunningham FG: *Williams Gynecology*: http://www.accessmedicine.com

Graft fixation.

7. **Incision Closure.** The vulvar incision is re-approximated along its length with interrupted subcuticular closure using 3-0 delayed-absorbable suture. The vaginal mucosa overlying the fistula is closed with a continuous running technique using 3-0 delayed-absorbable suture.

Postoperative

Care after surgery is dictated predominantly by the associated fistula repair. However, sitz baths twice daily typically are added to improve pain and healing of the vulvar incision.

42-12 SACRAL NEUROMODULATION

Sacral neuromodulation is a technique that delivers electrical stimulation to the pelvic plexus and pudendal nerves. This device is a Food and Drug Administration (FDA)â€"approved treatment for urinary urgency, frequency, urge incontinence, and for nonobstructive urinary retention. Although not FDA approved for pelvic pain and interstitial cystitis, it is sometimes used for these indications if they are associated with urgency, frequency, or retention. This surgery typically is performed for women who have failed to improve adequately from multiple other conservative therapies. The mechanism of action is unclear, but it is believed to modulate reflex pathways involved in bladder storage and emptying and innervation of the pelvic floor.

Sacral neuromodulation generally is completed in two steps. In the first stage, a lead is placed into the sacrum and connected to an external stimulus generator via an extension device. A test stimulation period of approximately 2 weeks follows. If symptoms are

decreased by 50 percent over the next several weeks, then a long-term use implantable pulse generator (IPG) is placed in the superior buttock fat in a second surgical procedure.

Preoperative

PATIENT EVALUATION

Prior to surgery, women should have completed a full evaluation, including urodynamic testing, voiding diary, cystoscopy, and other selected tests.

CONSENT

After the first stage, a 50-percent improvement in symptoms is considered a benchmark of success. Approximately, 75 percent of patients achieve this level of improvement and are candidates for IPG placement. Common complications following stage one include lack of clinical response or infection. For those who undergo second-stage implantation, approximately 80 percent reach the improvement benchmark and have greater than 50-percent improvement in symptoms.

Following the second stage, pain at the IPG site, infection, and lack of clinical response are common complications. After sacral neuromodulation, magnetic resonance (MR) imaging and security wanding at airport security checkpoints are contraindicated.

Intraoperative

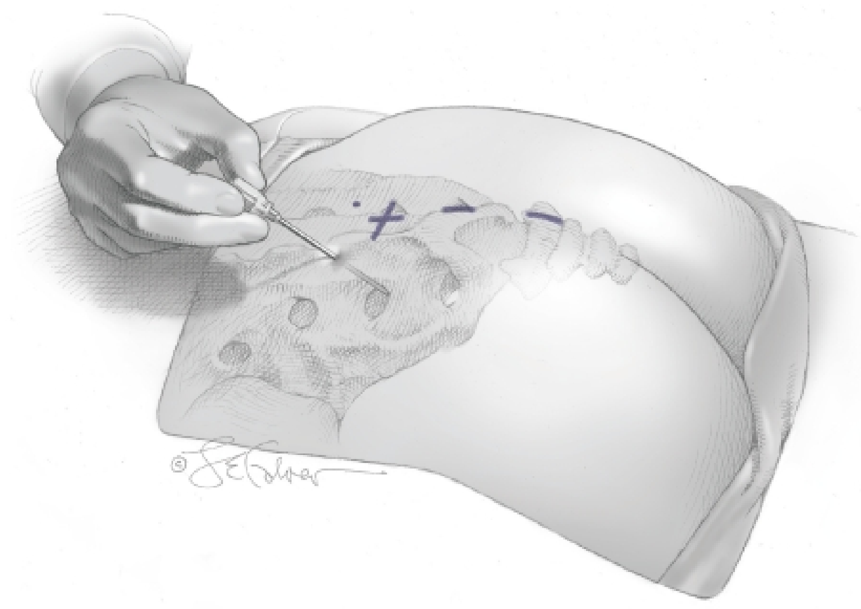
Surgical Steps

1. **Anesthesia and Patient Positioning.** Prior to surgery, antibiotics are administered. The patient is positioned prone on a Wilson frame or with a pillow under the abdomen and knees. The buttocks are separated to allow visualization of anus and perineum. General anesthesia is required to protect the airway, but neuromuscular blockade is contraindicated because this will prohibit neuromuscular stimulation evaluation. The sacrum and perianal areas are surgically prepared. A Foley catheter typically is not required because of the surgery's brevity.

2. **Identification of S3 Foramina.** These landmarks are the site of lead placement and are located approximately 9 cm above the coccyx and 1 to 2 cm lateral to the midline. Foramina are outlined with a surgical marker. A foramen needle is placed horizontally at the suspected level of S3, and a confirmatory fluoroscopic image is obtained.

3. **Foramen Needle Insertion.** The needle is inserted into the skin above the foramina and is guided at a 60-degree angle caudally into the opening (Fig. 42-12.1). If possible, the lead is placed concordant with patient handedness. Pelvic floor reflexes are checked, and when appropriate S3 reflexes are obtained, lead placement is initiated.

FIGURE 42-12.1



Source: Schorge JO, Schaffer JI, Halvorson LM, Hoffman BL, Bradshaw KD, Cunningham FG: *Williams Gynecology*: http://www.accessmedicine.com

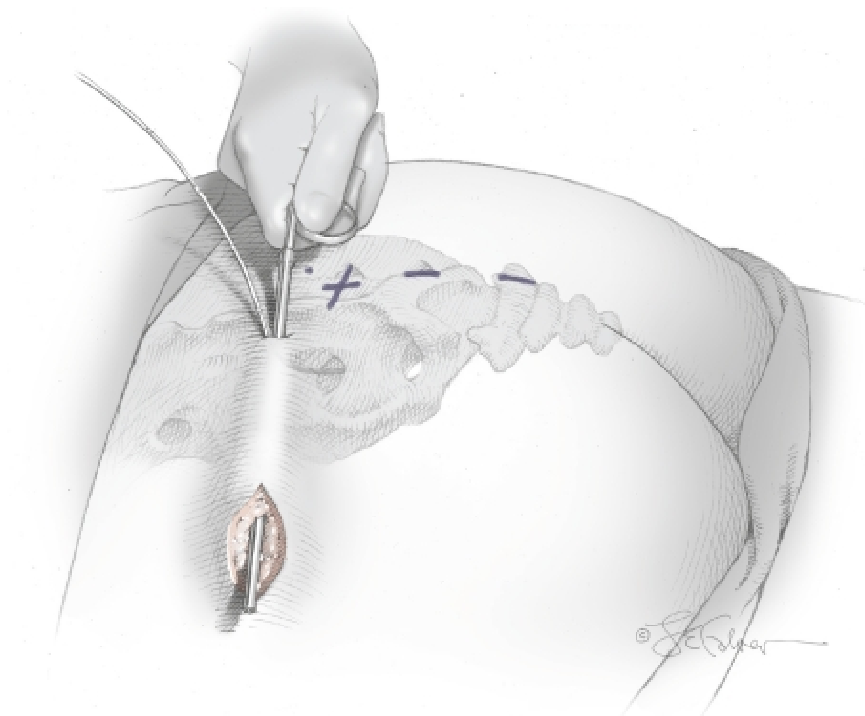
Foramen needle insertion.

4. **Lead Placement.** A guidewire is placed down the foramen needle under fluoroscopic guidance. The needle then is removed, and a small stab incision is made at the point where the guidewire enters the skin. A lead introducer then is passed over the guidewire into the foramina, again under fluoroscopic guidance. The guidewire is removed. With continued fluoroscopy, the tined lead then is passed down the introducer into the appropriate position at the S3 foramina. All four electrodes on the lead are tested for S3 pelvic floor reflexes, and after the lead is positioned correctly, the lead introducer is removed. The tines lock into place within the foramina when the trocar is removed. Thus, the leads cannot be repositioned after this point.

5. **Pulse Generator Incision and Lead Passage.** A 4- to 6-cm incision is made over the lateral buttock. Sharp and blunt dissection is used to create a deep pocket that can house the percutaneous lead extension for the temporary external pulse generator and eventually the permanent IPG. The pocket should be deep enough into the subcutaneous tissue that it does not indent the skin, but it should not sit directly above the muscle.

   After a pocket is created, a tunneling device is used to feed the lead from the midline incision into the pocket (Fig. 42-12.2).

FIGURE 42-12.2



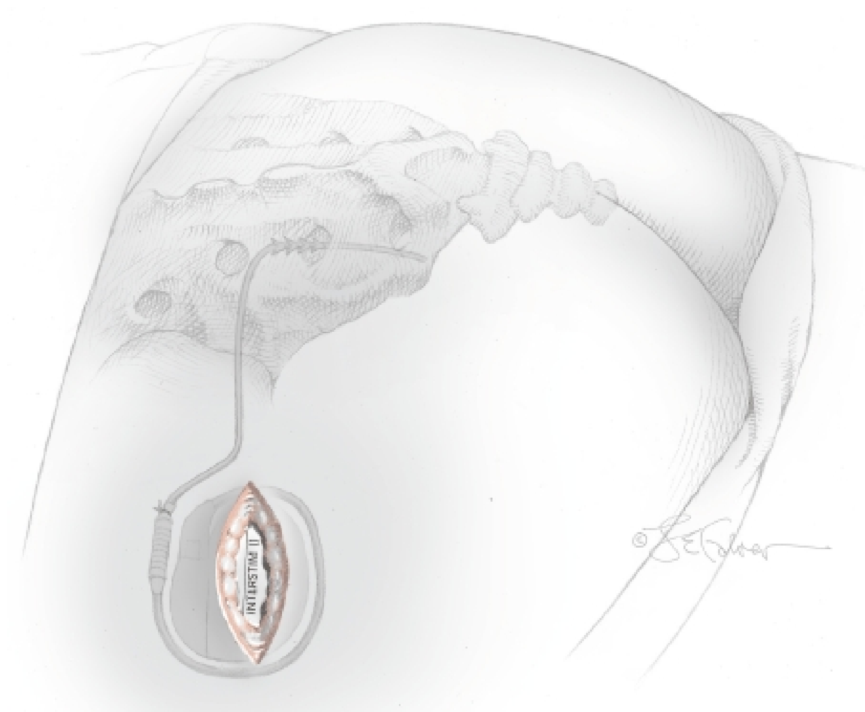
Source: Schorge JO, Schaffer JI, Halvorson LM, Hoffman BL, Bradshaw KD, Cunningham FG: *Williams Gynecology*: http://www.accessmedicine.com

Pulse generator incision and lead passage.

6. **Placement of the Percutaneous Lead Extension (First Stage).** Extending from the S3 foramina, the lead is connected to the percutaneous lead extension. A stab incision then is created lateral to the pocket, and the tunneling device is used to guide the percutaneous lead extension through the pocket and out the stab incision. The subcutaneous tissue then is closed over the connector with 2-0 delayed-absorbable suture in a running fashion. The skin is closed with a subcuticular stitch using 4-0 delayed-absorbable suture and dermabond. The percutaneous lead extension is connected to a temporary external pulse generator, which is used for 1 to 4 weeks to assess neuromodulation efficacy.

7. **Implantable Pulse Generator Placement (Second Stage).** If significant relief of symptoms is obtained, the permanent IPG is placed 1 to 4 weeks after the initial surgery. The procedure is performed with the patient prone and usually with general anesthesia for airway control. The lateral incision is opened down to the percutaneous lead extension, and the previously created pocket is re-opened. The connector and percutaneous lead extension are removed, and the permanent IPG is connected directly to the lead (Fig. 42-12.3). The incision is closed as step 6.

FIGURE 42-12.3



Source: Schorge JO, Schaffer JI, Halvorson LM, Hoffman BL, Bradshaw KD, Cunningham FG: *Williams Gynecology*: http://www.accessmedicine.com

Implantable pulse generator placement.

Postoperative

Pain or erythema at the incision site suggests cellulitis, abscess, or seroma. These symptoms should be evaluated as soon as possible, with institution of antibiotics if needed. Unusual pain also should be evaluated immediately because this could suggest lead malfunction. A woman can turn the device off by herself if necessary.

Symptoms are continually assessed postoperatively, and the IPG is reprogrammed as needed. Reprogramming the device or changing leads often can improve refractory symptoms.

42-13 ANTERIOR COLPORRHAPHY

Anterior colporrhaphy is one of the more commonly performed gynecologic surgeries. Although it is still used as a primary choice for repair of anterior vaginal wall prolapse (cystocele), randomized trials suggest that anatomic cure is obtained in 50 percent of patients or less (Weber, 2001). Therefore, several different techniques are used to augment traditional anterior colporrhaphy, including vaginal paravaginal defect repair (PVDR) and re-inforcement with synthetic or biologic mesh.

During traditional anterior colporrhaphy procedure (midline plication), attenuated supporting connective tissue between the vagina and bladder is reapproximated and reinforced using plication sutures. This bolstering along the length of the vagina attempts to elevate the bladder and urethra to a more anterior and anatomically normal position. The vaginal PVDR attempts to provide lateral support to the anterior vaginal wall. Mesh augmentation procedures may be used to add tissue strength and provide lateral and midline support.

In observational series, success rates for mesh augmentation range from 93 to 100 percent after 2 years (Julian, 1996; Mage, 1999; Migliari, 1999). In randomized studies, however, rates of improvement in excess of those found with with traditional colporrhaphy are more modest, approximating 15 percent (Sand, 2001; Weber, 2001). Additionally, the associated risks of mesh

erosion and infection should be factored into any decision to add reinforcing mesh (Cervigni, 2001). Cadaveric fascia has been used similarly. Gandhi (2005), however, found no improved rates of surgical success using this material.

In women with cystocele, other points of pelvic support also may require concurrent repair. Accordingly, anterior colporrhaphy is performed frequently in combination with corrective surgeries for enterocele, rectocele, and vaginal apex prolapse.

Preoperative

PATIENT EVALUATION

Women with anterior vaginal wall prolapse commonly have associated stress urinary incontinence (SUI) (Borstad, 1989). Even those who are continent, however, may have SUI unmasked following anterior vaginal wall prolapse correction. Thus, preoperative urodynamic evaluation is recommended. During this evaluation, the prolapse is reduced to its anticipated postoperative position to mimic pelvic floor dynamics following surgery (Chaikin, 2000; Yamada, 2001). The decision to perform a concurrent prophylactic anti-incontinence procedure then is dictated by individual urodynamic findings.

CONSENT

For most women, anterior colporrhaphy has low rates of complications. Of these, recurrence of the anterior vaginal wall defect is one of the most common. Several factors have been noted to increase this risk and include a large original defect and an increased number of other prolapsed pelvic compartments. In addition to prolapse recurrence, postoperative dyspareunia has been noted. Less frequently, serious hemorrhage or cystotomy may complicate this procedure. If mesh is used, erosion or extrusion is a risk.

PATIENT PREPARATION

To decompress the rectum and thereby increase operating space within the vagina, bowel preparation typically is administered the evening prior to surgery. Antibiotic prophylaxis with a first- or second-generation cephalosporin is recommended immediately prior to surgery.

Intraoperative

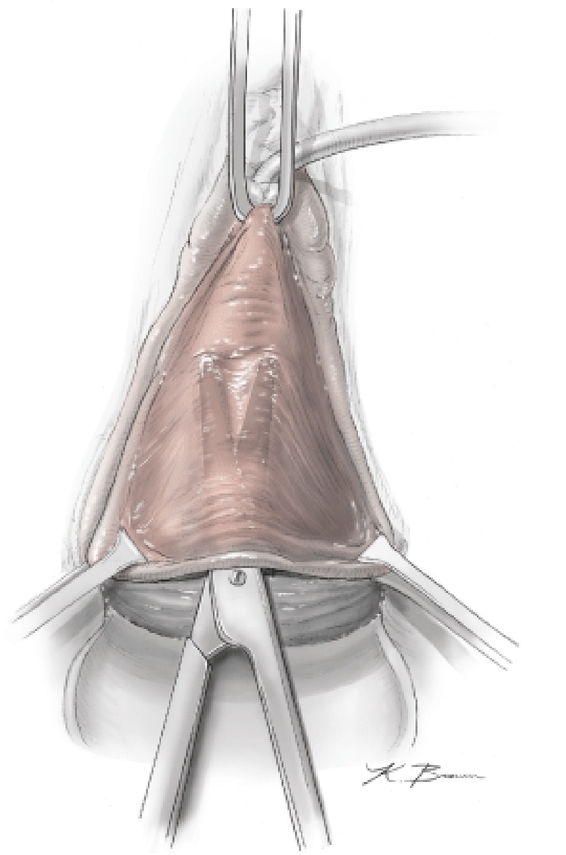
Surgical Steps

1. **Anesthesia and Patient Positioning.** After adequate general or regional anesthesia is administered, the patient is placed in the dorsal lithotomy position, the vagina is surgically prepared, and a Foley catheter is placed. An Auvard weighted speculum is positioned to retract the posterior vaginal wall.

2. **Concurrent Surgery.** If other reconstructive surgeries are required, they may precede or follow anterior colporrhaphy. Anterior colporrhaphy may be performed with the uterus in situ or alternatively, completed following hysterectomy.

3. **Vaginal Incision.** One to 2 cm distal to the vaginal apex, an Allis clamp is placed on each side of the anterior vaginal wall (Fig. 42-13.1). These clamps are gently pulled laterally to create tension, and the vaginal wall between them is incised transversely. Following incision, a third clamp is placed in the midline 3 to 4 cm distal to this incision (Fig. 42-13.1). All three clamps are held, creating gentle outward tension.

FIGURE 42-13.1



Source: Schorge JO, Schaffer JI, Halvorson LM, Hoffman BL, Bradshaw KD, Cunningham FG: *Williams Gynecology*: http://www.accessmedicine.com

Tissue plane dissection.

4. **Tissue Plane Dissection.** The tips of curved Metzenbaum scissors are insinuated beneath the vaginal mucosa. Opening and closing the scissor blades while exerting gentle forward pressure within the plane underlying the vaginal mucosa allows separation from the fibromuscular layer (Fig. 42-13.1). This dissection continues distally to reach the midline Allis clamp. The undermined vaginal wall then is incised longitudinally.

   Additional Allis clamps are placed, one on each freed mucosal edge. The more distal central Allis clamp is moved 3 to 4 cm further distally. The steps of vaginal wall dissection then are repeated. This process continues until the wall has been bisected and dissected to within 2 to 3 cm of the urethral meatus. This ending spot corresponds to a midpoint along the length of the urethra.

   The lateral attachments of the vaginal wall to the underlying fibromuscular layer are separated next. Allis clamps are placed on the cut vaginal edges and fanned laterally to create tension (Fig. 42-13.2). With one finger behind the vaginal wall, the scissors are held parallel to the wall, and the epithelial layer is dissected sharply from the fibromuscular layer (Fig. 42-13.3). A combination of sharp and blunt dissection is used, and once the proper tissue plane is entered, the layers separate readily. This dissection is extended laterally and almost reaches the pubic rami.

FIGURE 42-13.2

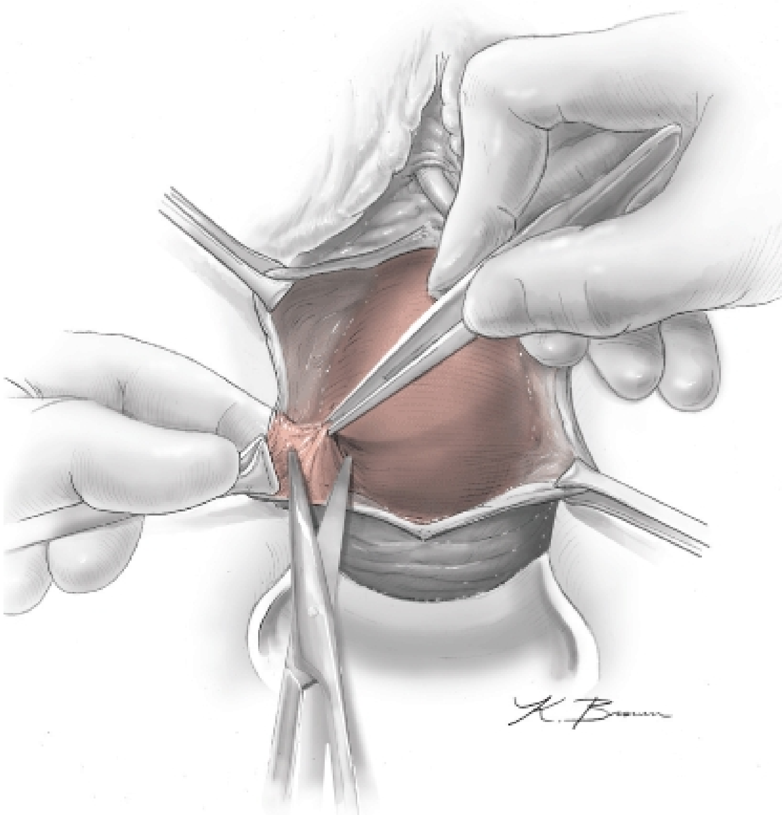
Vaginal incision.

FIGURE 42-13.3

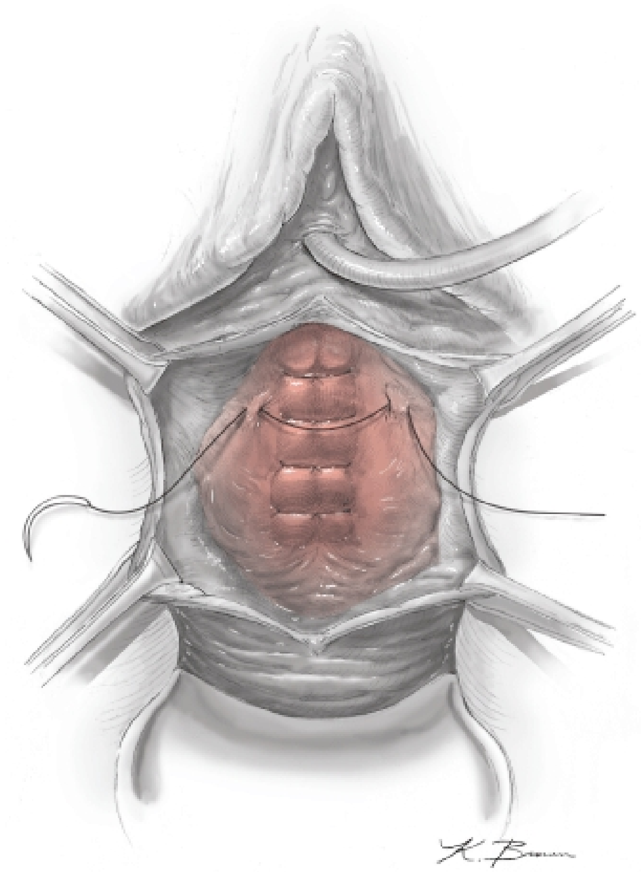


Source: Schorge JO, Schaffer JI, Halvorson LM, Hoffman BL, Bradshaw KD, Cunningham FG: *Williams Gynecology*: http://www.accessmedicine.com

Separation of mucosa and fibromuscular layer.

5. **Traditional Anterior Coloporrhapy (Midline Plication).** Plication of the fibromuscular layer then is begun. Interrupted sutures of 2-0 permanent or delayed-absorbable suture on an SH needle are placed in the midline along the length of the vaginal wall (Fig. 42-13.4). Plication of the fibromuscular layer creates a double layer of support for the bladder and urethra. Tissue tension should create a firm shelf overlying the bladder, but extreme tension is avoided to prevent sutures from pulling through the fascia or excessively narrowing the vagina. As sutures are tied, the bladder is pushed by the surgeon gently upward and away from the incision line. A second layer of plication sutures is placed beginning lateral to the first, if necessary (Fig. 42-13.4).

FIGURE 42-13.4



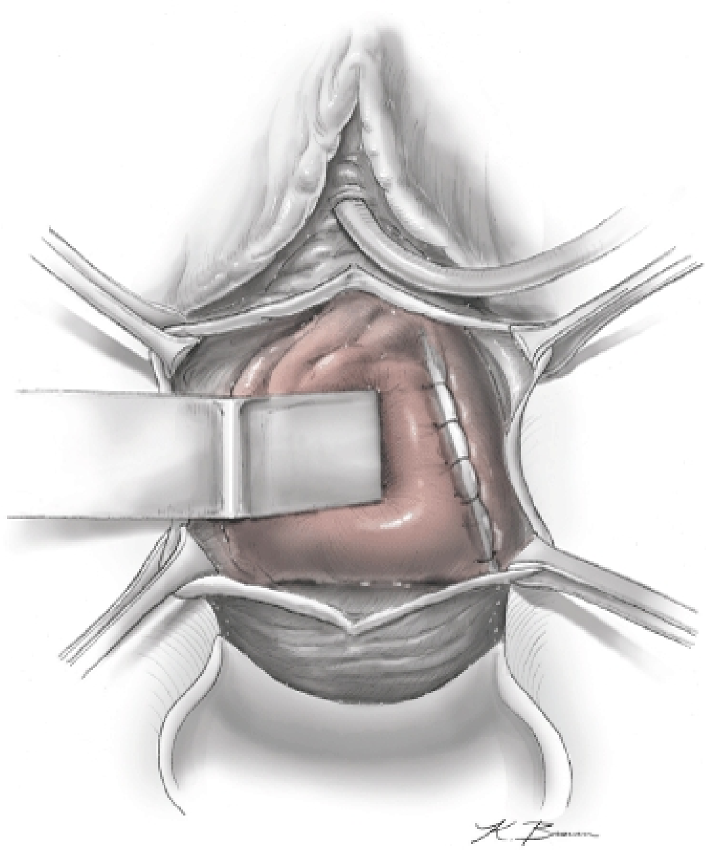
Source: Schorge JO, Schaffer JI, Halvorson LM, Hoffman BL, Bradshaw KD, Cunningham FG: *Williams Gynecology*: http://www.accessmedicine.com

Midline plication.

6. **Vaginal Paravaginal Defect Repair.** For women with anterolateral vaginal wall defects, vaginal PVDR may be used primarily. If PVDR is to be performed, lateral dissection proceeds along the ischipubic rami from the pubic symphysis to the ischial spine. Blunt dissection is used to enter the space of Retzius. If a paravaginal defect is present, the space is entered easily. The arcus tendineus fascia pelvis is seen as a white line running from the ischial spine to the symphysis. Visualization is aided with the use of Breisky-Navratil and lighted retractors (see Fig. 40-20).

   A series of four to six 0-gauge permanent sutures are placed in the arcus tendineus or obturator fascia and attached to the lateral edge of the vaginal fibromuscular layer (Fig. 42-13.5). This is then repeated on the other side. If necessary a midline plication can be performed after the vaginal paravaginal sutures are tied, however, the vagina wall should not be placed on tension.

FIGURE 42-13.5

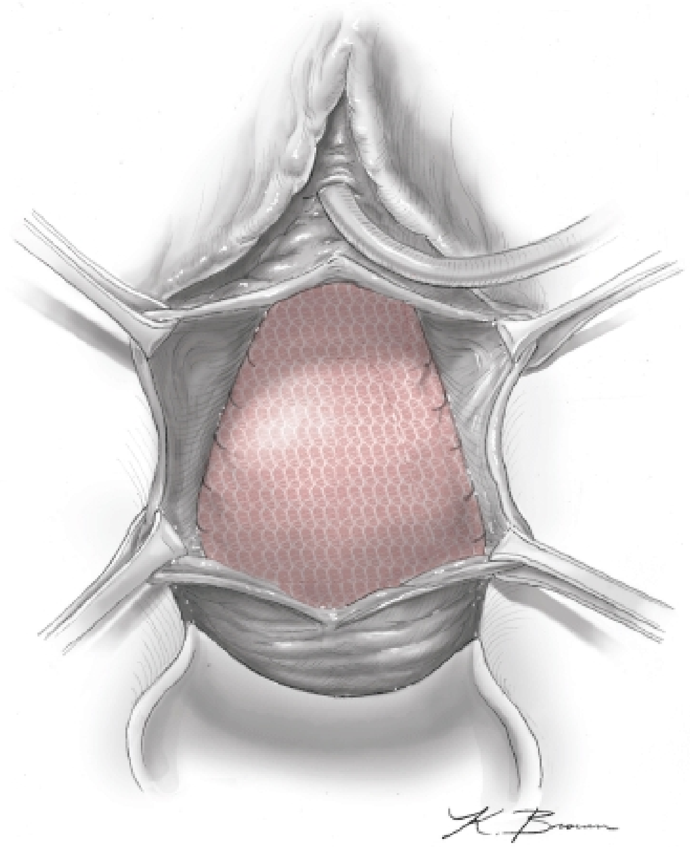


Source: Schorge JO, Schaffer JI, Halvorson LM, Hoffman BL, Bradshaw KD, Cunningham FG: *Williams Gynecology*: http://www.accessmedicine.com

Vaginal paravaginal defect repair.

7. **Mesh Augmentation.** For the mesh augmentation procedure, dissection proceeds similar to that for the PVDR. The mesh is cut in a trapezoidal shape and is attached to the arcus tendineus with four 2-0 permanent sutures on each side (Fig. 42-13.6). Mesh augmentation may be used solely to re-inforce an anterior wall defect or may be used after midline plication, as described earlier (step 5).

FIGURE 42-13.6

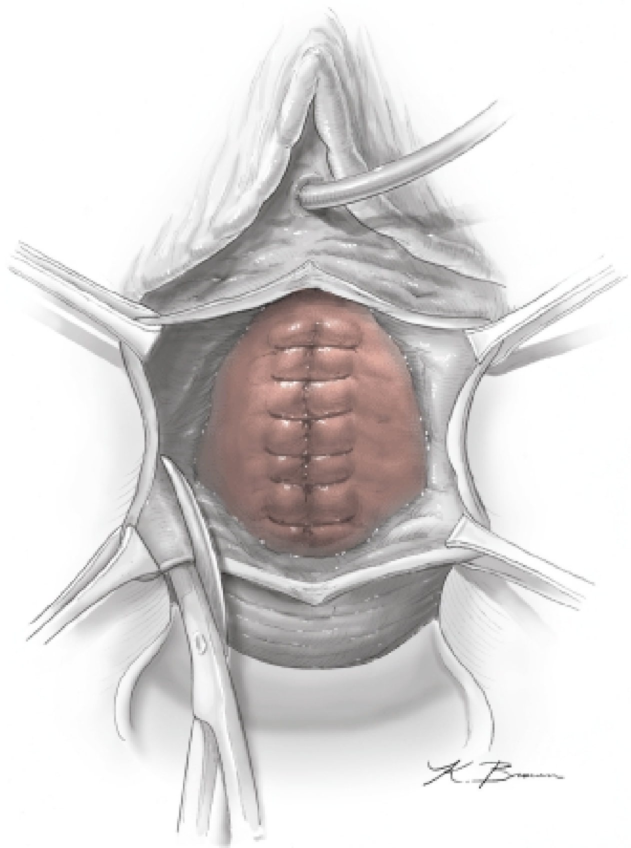


Source: Schorge JO, Schaffer JI, Halvorson LM, Hoffman BL, Bradshaw KD, Cunningham FG: *Williams Gynecology*: http://www.accessmedicine.com

Mesh final placement.

8. **Incision Closure.** Depending on the size of the original cystocele, some redundant vaginal wall likely will be present and require trimming (Fig. 42-13.7). Liberal trimming, however, can place the vaginal wall incision on excessive tension, affect wound healing, and narrow the vagina. Therefore, care should be taken to minimized tissue excision. The vaginal mucosa is re-approximated using a running suture with a 2-0 delayed-absorbable suture.

FIGURE 42-13.7



Source: Schorge JO, Schaffer JI, Halvorson LM, Hoffman BL, Bradshaw KD, Cunningham FG: *Williams Gynecology*: http://www.accessmedicine.com

Second layer of plication and excess mucosa trimmed.

9. **Cystoscopy.** Kwon and colleagues (2002) performed cystoscopy following 346 anterior colporrhaphy procedures and found unexpected injury in 2 percent of patients. These each required suture removal and replacement. Accordingly, cystoscopy may be warranted to document the integrity of the ureteral orifices, bladder, and urethral lumen.

Postoperative

Recovery following anterior colporrhaphy for most women is rapid and associated with few complications. Urinary retention or urinary tract infection, however, is common. In anticipation of retention, many surgeons advocate bladder drainage until urine residuals fall below 200 mL.

As with other vaginal surgery, diet and activity can be advanced as tolerated. Women, however, should abstain from intercourse until complete wound healing, typically at 6 to 8 weeks following repair.

42-14 ABDOMINAL PARAVAGINAL DEFECT REPAIR

Paravaginal defect repair (PVDR) is a prolapse procedure that corrects lateral defects in the anterior vaginal wall. The procedure involves attachment of the lateral vaginal wall to the arcus tendineus fascia pelvis (see Fig. 38-25). Over the last 20 years, PVDR has become popular as we have gained a deeper understanding of the importance of lateral defects in anterior vaginal wall

prolapse pathophysiology.

Paravaginal defect repair is primarily a prolapse operation and has not been shown to be an effective treatment for stress urinary incontinence (SUI). This repair can be performed alone or in combination with other prolapse procedures. For example, PVDR frequently is performed in conjunction with the Burch procedure (see Section 42-2, Burch Colposuspension). Paravaginal defect repair provides support to the middle and upper vagina, whereas the Burch procedure provides middle and distal support.

Paravaginal defect repair also can be performed laparoscopically by those with advanced laparoscopic skills. If sutures can be placed the same as in the abdominal approach, the results are expected to be equivalent.

Preoperative

PATIENT EVALUATION

Demonstration of lateral vaginal wall defects on physical examination is required prior to surgery. These are outlined in Chapter 24, Visual Descriptors. If significant anterior wall prolapse is identified, evaluation for SUI or potential SUI should be pursued. In women who have an isolated paravaginal defect, there is the risk that other pelvic support defects such as apical or posterior vaginal prolapse may develop. Thus, attempts to identify these potential defects should precede surgery. In some instances, prophylactic repair of potential defects is indicated.

CONSENT

Paravaginal defect repair provides effective support to the lateral vaginal walls, but as with other prolapse procedures, long-term success rates diminish with time. The procedure involves surgery in the space of Retzius, which has the potential for significant blood loss. In particular, those who have had prior surgery in this space are at increased risk of significant hemorrhage. Inaccurate suture placement can result in injury to the bladder and/or ureters, although this is uncommon, especially in the hand of an experienced surgeon. Additional complications include postoperative urinary incontinence or retention.

PATIENT PREPARATION

To prevent wound infection, antibiotic prophylaxis is given (see Chap. 39, Surgical Site Infection Prophylaxis). It is our practice to recommend bowel preparation prior to PVDR to decompress the bowel, although this practice is not mandatory. However, if this procedure is performed in combination with more extensive pelvic reconstructive surgeries, then thorough bowel evacuation is warranted (see Table 39-10).

Intraoperative

Surgical Steps

1. **Anesthesia and Patient Positioning.** This surgery typically is performed as an inpatient procedure under general or regional anesthesia. Following administration of anesthesia, the patient should be positioned in low lithotomy using Allen stirrups. Adequate exposure to the vagina is vital because a vaginal hand is used to elevate and dissect the paravaginal space. The abdomen and vagina are surgically prepared, and Foley catheter with a 10-mL balloon is placed.

2. **Abdominal Incision.** A low transverse incision placed 1 cm superior to the symphysis pubis affords the best exposure to the space of Retzius (see Section 41-2, Pfannenstiel Incision). Entry into the peritoneal cavity is not necessary, however, this may assist in placement of a self-retaining retractor.

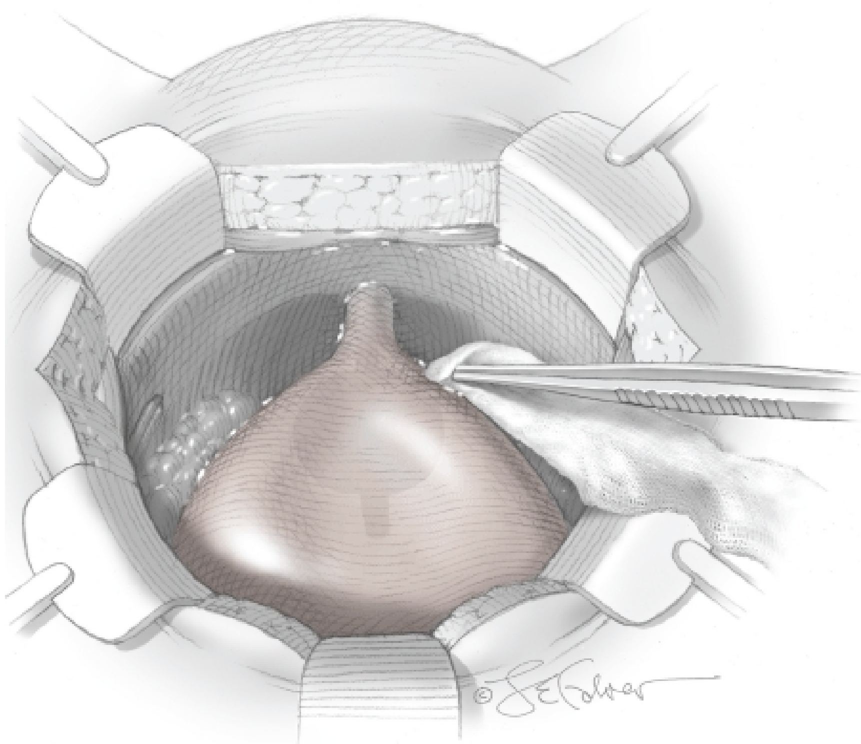
3. **Entering the Space of Retzius.** After incision of the fascia, the rectus muscles are separated in the midline, and retractors are used to hold them in apposition. Careful dissection of this space decreases the risk of hemorrhage and creates accurate tissue planes for suture placement. The correct plane of dissection for opening the space of Retzius is directly behind the pubic bone. Loose areolar tissue is dissected gently in a mediolateral fashion with fingers or sponge beginning immediately behind the pubic bone (Fig. 42-14.1). If the correct plane is entered, this avascular potential space opens easily and without significant hemorrhage. If bleeding does occur, it is likely that the wrong tissue plane had been entered.

   After the medial portion of the space of Retzius is opened, the obturator canal should be palpated bilaterally so that the vessels and nerve within this area can be avoided (see Fig. 38-25). The ischial spine then is palpated 4 to 5 cm directly below

the obturator canal. The remainder of the paravaginal space is opened with gentle finger dissection or gentle insertion of 4 x 4 in gauze sponges into the lateral paravaginal spaces. This is aided by a vaginal hand pushing up into the space.

Large paravaginal blood vessels are noted along the lateral vaginal wall. Bleeding of these vessels is controlled easily by upward pressure of the vaginal hand while hemostatic sutures are placed.

FIGURE 42-14.1



Source: Schorge JO, Schaffer JI, Halvorson LM, Hoffman BL, Bradshaw KD, Cunningham FG: *Williams Gynecology*: http://www.accessmedicine.com

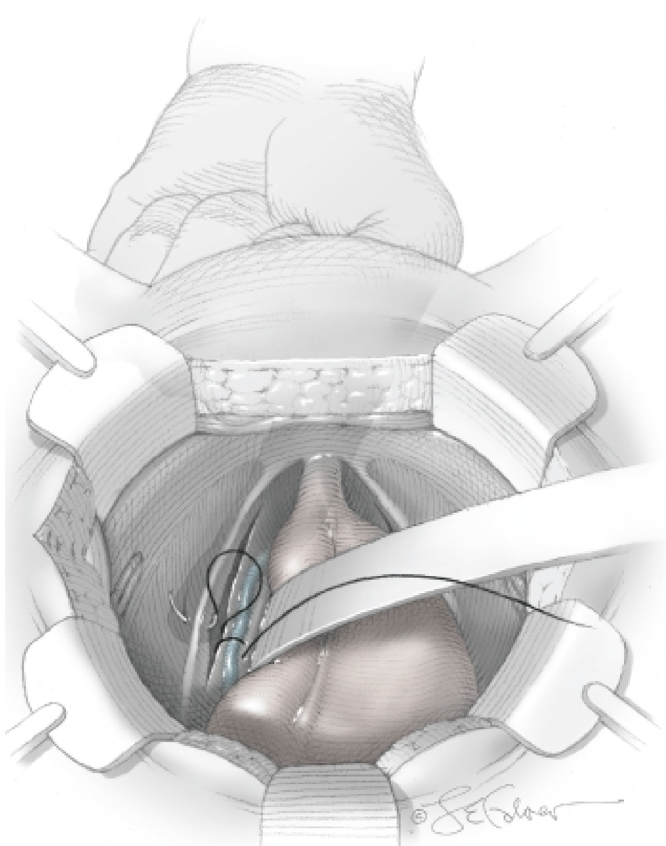
Dissection in the space of Retzius.

4. **Identification of the Arcus Tendineus Fascia Pelvis.** The arcus tendineus fascia pelvis runs between the pubic symphysis and the ischial spine (see Fig. 38-25). It is observed in this location along the sidewall as a condensation of white connective tissue. In those with defects, it may be torn in the middle or completely avulsed from the sidewall.

5. **Placement of Paravaginal Sutures.** With a hand in the vagina pressing upward into the paravaginal space, a medium-sized malleable retractor is used to reflect the bladder medially and protect it from inadvertent suture placement.

   The most cephalad suture is the first one placed (Fig. 42-14.2). The vaginal finger presses upward, against the lateral vaginal wall, and a figure-of-eight stitch with 2-0 permanent suture is placed around the paravaginal vessels, taking care to avoid entry into the vaginal lumen. If bleeding follows, the suture is tied to constrict involved vessels. The suture then is placed through the arcus tendeneus fascia pelvis at a point 1 to 2 cm caudal to the ischial spine. Sutures are not tied until all paravaginal sutures have been placed. During suture placement, the obturator canal and neurovascular bundle should be visualized and avoided. Three to five more paravaginal stitches then are placed at 1-cm intervals until the level of the bladder neck is reached (Fig. 42-14.3). After all sutures are placed, they are tied, and the procedure is repeated on the other side of the vagina.

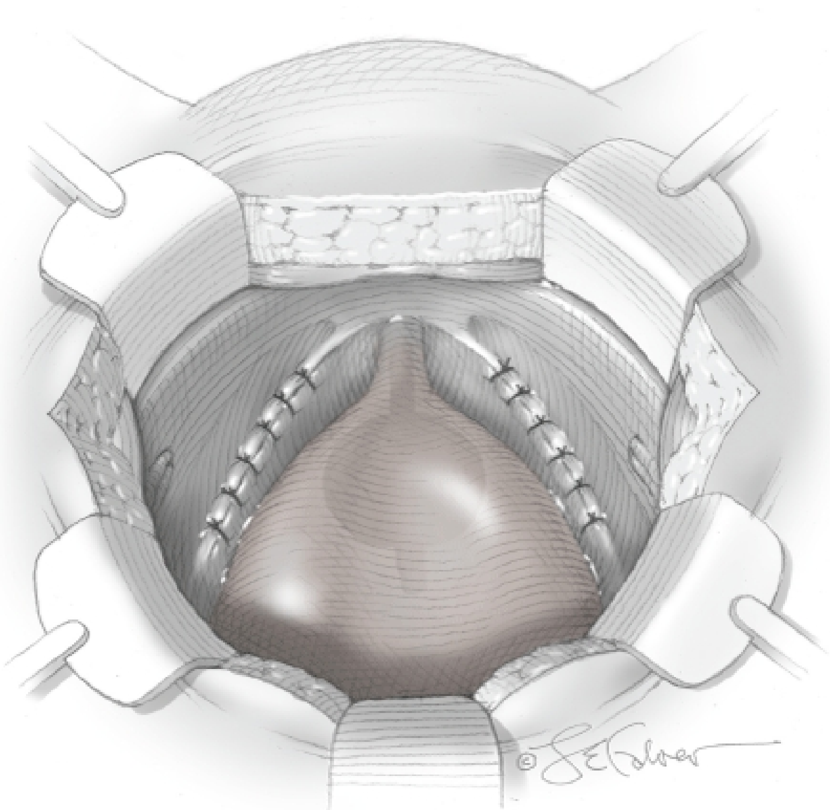
FIGURE 42-14.2



Source: Schorge JO, Schaffer JI, Halvorson LM, Hoffman BL, Bradshaw KD, Cunningham FG: *Williams Gynecology*: http://www.accessmedicine.com

Placement of paravaginal sutures.

FIGURE 42-14.3



Source: Schorge JO, Schaffer JI, Halvorson LM, Hoffman BL, Bradshaw KD, Cunningham FG: *Williams Gynecology*: http://www.accessmedicine.com

Final suture placement.

6. **Cystoscopy.** One half to 1 ampule of intravenous indigo carmine is administered intravenously, and cystoscopy is performed. Efflux from both ureteral orifices must be seen. In addition, the bladder surfaces should be inspected for sutures. A misplaced suture might be seen as a dimple in the bladder wall. If found, sutures entering the bladder should be removed and replaced properly.

7. **Incision Closure.** After vigorous irrigation of the space of Retzius, the abdomen is closed in a standard fashion (see Section 41-2, Pfannenstiel Incision). If the peritoneum was opened, closure is recommended to prevent small bowel adhesions in the space of Retzius.

8. **Concurrent Procedures.** In patients with stress urinary incontinence, a Burch procedure might be performed after placement of paravaginal sutures. In this case, cystoscopy is delayed until after the Burch procedure is completed.

Postoperative

In general, recovery follows that associated with laparotomy and varies depending on concurrent surgeries and incision size. A voiding trial as described in Chapter 39, Voiding Trials is performed prior to hospital discharge.

42-15 POSTERIOR COLPORRHAPHY

Posterior colporrhaphy traditionally is used to repair prolapse of the posterior vaginal wall (rectocele). Specifically, posterior

colporrhaphy techniques attempt to re-inforce the fibromuscular layer of tissue between the vagina and rectum to prevent prolapse of the rectum into the vaginal lumen.

In many situations, the apex of the posterior vaginal wall also must be suspended to obtain successful repair. Thus, if care is not given to apical descent, recurrent prolapse may follow. Additionally, perineorrhaphy often is carried out in conjunction with posterior colporrhaphy.

Variations of posterior colporrhaphy have been developed to improve success rates. Current methods include midline plication, defect-directed repair, and placement of re-inforcing materials. Evidence, however, does not indicate that one of these is more effective.

Preoperative

PATIENT EVALUATION

A detailed discussion of symptoms should begin every patient evaluation prior to colporrhaphy. Often patients may associate all their bowel symptoms to the presence of a posterior wall bulge, but the two may not be related. Specifically, if constipation is a major complaint, then a trial of nonsurgical treatment may be warranted. Symptoms most likely to be to cured by this procedure include the need to digitally decompress the rectal vault and the sensation of vaginal bulge.

Posterior wall prolapse commonly accompanies other support defects, and women should undergo a complete pelvic organ prolapse examination, as described in Chapter 24, Perineal Examination. If concurrent anterior vaginal wall or vaginal apical prolapse is present, this also should be repaired.

CONSENT

In addition to standard surgical risks, this procedure may be associated with failure to correct symptoms or anatomy. Therefore, a patient and surgeon should identify treatment goals and discuss expectations. In the few randomized studies that have been done, current techniques give a less than optimal anatomic repair, and success rates approximate 70 percent. An additional common risk includes dyspareunia. However, injury to the rectum is rare.

PATIENT PREPARATION

A thorough bowel preparation is indicated to prevent fecal contamination during surgery. Additionally, delay of immediate postoperative defecation may be beneficial for patient comfort and can be achieved with a clear-liquid or low-residual diet. Antibiotic prophylaxis with a first- or second-generation cephalosporin is recommended.

Intraoperative

Surgical Steps

1. **Anesthesia and Patient Positioning.** Posterior colporrhaphy typically is an inpatient procedure performed under general or regional anesthesia. A patient is place in high lithotomy position with stirrups of the surgeon's choosing, and the vagina is surgically prepared. A Foley catheter is not needed unless required by concurrent surgeries.

2. **Vaginal Incision and Dissection.** Corners of the introitus are grasped with Allis clamps. A third Allis clamp is placed in the vaginal midline at the proximal apex of the vaginal bulge. At the perineum, a horizontal incision is made and extended between the Allis clamps at the introitus.

   Metzenbaum scissors then are used to develop the incision by undermining the vaginal mucosa (Fig. 42-15.1). Because of fusion of the fibromuscular layer within the perineal body, as well as possible scarring from prior episiotomy, clear tissue planes are not present. Thus, in the area immediately adjacent to the perineal body, sharp dissection is required. Once the vaginal mucosa is reached, however, clear tissue planes typically are encountered, and blunt dissection can be combined with sharp dissection.

   During dissection, care should be taken to stay in the correct tissue plane. Deep dissection can lead to entry into the rectum, whereas superficial dissection can create defects in the vaginal mucosa, often called *button holes.* Dissection should extend cephalad to the level of the proximal Allis clamp previously placed at the apex.

A midline vertical incision then is made from the perineal incision to the apex using Metzenbaum scissors. The edges of the midline incision are grasped with Allis clamps. Additional bilateral sharp and blunt dissection typically is necessary to further separate the fibromuscular layer from the vaginal epithelium laterally.

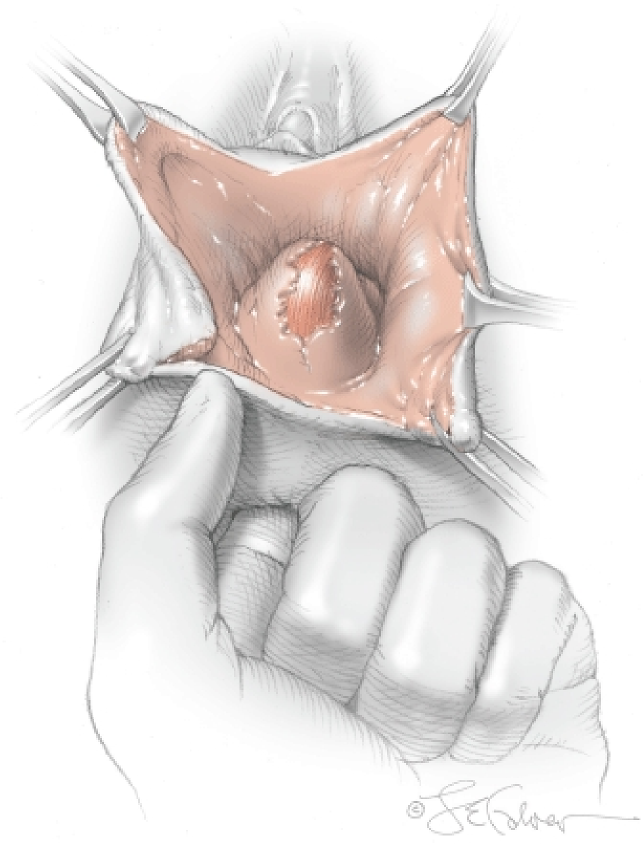
Vaginal incision and dissection.

3. **Rectal Examination.** Rectal examination is performed to identify the fibromuscular layer as well as the rectal wall and the levator ani muscles (Fig. 42-15.2).

FIGURE 42-15.2



Source: Schorge JO, Schaffer JI, Halvorson LM, Hoffman BL, Bradshaw KD, Cunningham FG: *Williams Gynecology*: http://www.accessmedicine.com

Rectal examination.

4. **Midline Plication.** A series of interrupted 2-0 delayed-absorbable or permanent sutures is used to plicate the vaginal muscularis in the midline, and the line of plication sutures extends from the apex to the perineum (Figs. 42-15.3 and 42-15.4). A second layer of interrupted sutures then plicates muscularis that lies lateral to tissues approximated with the first layer. These sutures are secured in the midline over the first layer.

   Care must be taken to avoid placement of sutures too far laterally because this will lead to a tissue bridge in the posterior vaginal wall with resulting dyspareunia. Additionally, sutures should not be placed in the levator ani muscles because this also may produce dyspareunia and chronic pain. Rectal examination should be performed after all sutures are placed to exclude inadvertent suture placement into the rectum.

   Re-inforcement of the apical aspect of the posterior vaginal wall often is beneficial. If the uterosacral ligaments are identified at the lateral corners of the apex, interrupted sutures are used to connect these ligaments to the upper posterior wall fibromuscular layer.

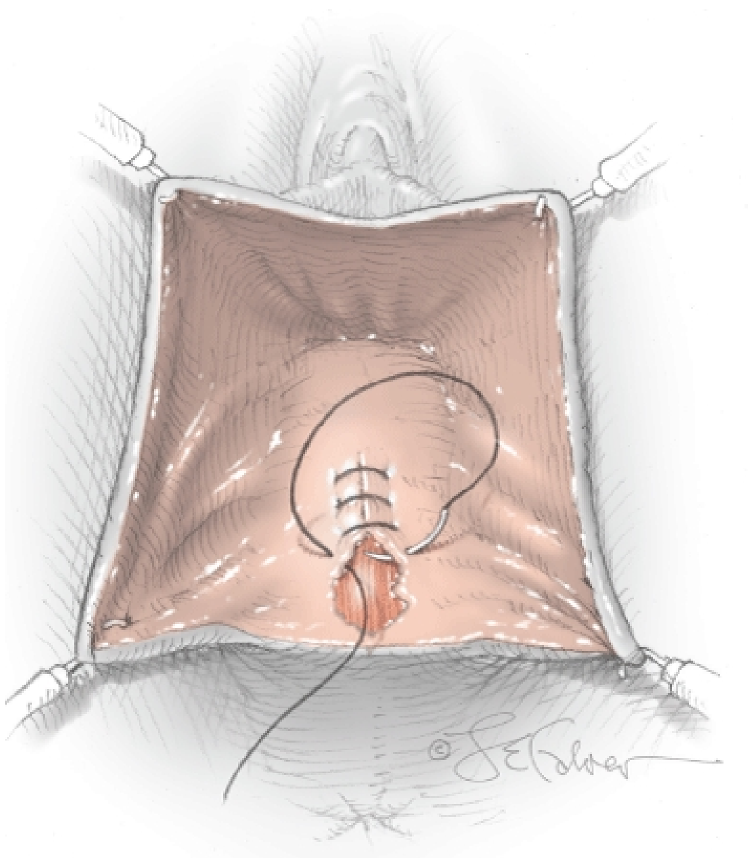
Midline plication.

FIGURE 42-15.4



Midline plication.

5. **Defect-Directed Repair.** In some instances, a discrete defect is identified in the posterior fibromuscular layer after the initial dissection. Defects may be lateral, midline, apical, or perineal (Figs. 42-15.5, 42-15.6, 42-15.7, 42-15.8, 42-15.9, and 42-15.10). In this situation, midline plication may not be effective, and a defect repair should be performed. Interrupted stitches of 2-0 permanent or delayed-absorbable sutures are used to close the defect. This is generally a one-layered closure.

Defect-directed repair.

6. **Mesh Augmentation.** In situations in which good fibromuscular tissue cannot be identified, synthetic or biologic material can be used for augmentation (Fig. 42-15.11). The initial epithelial dissection is continued laterally and to the apex. The material to be used is cut to size so that it lies flat. It is then sutured with interrupted stitches of 2-0 delayed-absorbable suture to the vaginal apex as well as to the distal and lateral edges of the fibromuscular layer (Fig. 42-15.12). If permanent mesh is used, it should be kept at least 2 cm from the perineal body. The risk of mesh erosion increases as mesh is placed closer to the perineal body. Finally, if the need for mesh augmentation is anticipated, initial dissection is made in a deeper tissue plane to create greater distance between the mesh and vaginal lumen. This hopefully lowers the chance of mesh erosion into the vagina.

Mesh augmentation.

7. **Perineorrhaphy.** Perineorrhaphy often is performed in conjunction with posterior repair (see Section 42-16, Perineorrhaphy). If performed, it typically follows closure of the vaginal incision.

8. **Incision Closure.** Following plication, redundant vaginal wall often remains and requires trimming. Liberal trimming, however, can narrow the vagina and can place the vaginal wall incision on excessive tension and impair wound healing.

   The vaginal mucosa is reapproximated in a running fashion using a 2-0 delayed-absorbable suture. Care should be taken to avoid placement of suture bites too far apart. Widely positioned sutures can lead to accordion-type bunching of the vaginal epithelium and subsequent shortening of the vagina when the final knot is tied.

Postoperative

Patients are instructed to use twice-daily Sitz bath, stool softeners, and high-fiber diets. Constipation must be meticulously avoided. Intercourse is delayed until evaluation at 1 month postoperatively.

42-16 PERINEORRHAPHY

The perineal body serves as core support of the distal aspect of the vagina, rectum, and pelvic floor. Therefore, a damaged or weakened perineal body may contribute to distal prolapse. Re-inforcement of this structure, that is, perineorrhaphy, often is performed in conjunction with other reconstructive procedures, such as posterior colporrhaphy. As a result of this procedure, a shortened perineal body is lengthened, and the genital hiatus is shortened concurrently to re-establish distal support.

Preoperative

PATIENT EVALUATION

The length of the genital hiatus is measured in centimeters both at rest and with Valsalva maneuver from the urethral meatus at 12 o'clock to the hymeneal ring at 6 o'clock. The perineal body is measured from the hymeneal ring at 6 o'clock to the anus (see Chap. 24, Anterior Vaginal Wall Points). Normative data for these lengths do not exist. Therefore, the decision for perineorrhaphy must include an overall assessment of patient symptoms, clinical findings, and anatomy.

Perineorrhaphy is also sometimes performed for laxity of the introitus with the goal of narrowing the genital hiatus. However, care must be taken not to decrease the caliber to the extent that dyspareunia results. Moreover, in sexually active postmenopausal women whose partners have decreased erectile tone, entry into the vagina may be difficult if the introitus is too small.

CONSENT

A patient preparing for perineorrhaphy should be counseled about risks of postoperative dyspareunia, prolapse recurrence, or wound complications, such as a stitch abscess.

PATIENT PREPARATION

Because of the surgical site's close proximity to the anus, and also because bowel injury is possible, bowel preparation and antibiotic prophylaxis are administered prior to surgery. These are given to minimize the risks of fecal contamination and wound infection.

Intraoperative

Surgical Steps

1. **Anesthesia and Patient Positioning.** Perineorrhaphy typically is performed under general or regional anesthesia, and this choice is often dictated by concurrent surgeries planned. The patient is placed in dorsal lithotomy position. A vaginal and rectal examination under anesthesia is performed first to assess the size of the perineal body and defects of the posterior vaginal wall, which also may require repair. The vagina is surgically prepared, and a Foley catheter is placed.

2. **Concurrent Surgery.** If concurrent surgeries have been included, perineorrhaphy in most cases is the final procedure.

3. **Incision.** To determine the approximate appearance of the final repair, Allis clamps are placed at the corners of the introitus at 3 and 9 o'clock. These are brought together in the midline. With this technique, the surgeon can judge the final size of the introitus and perineal body anticipated at the procedure's conclusion. Because scarring and retraction can follow surgery, it is prudent to err on the side of leaving the genital hiatus larger rather than smaller. Although each case is individualized, in general, the introitus should admit three fingers at the end of surgery.

   A diamond-shape incision is made with its cephalad tip extending 2 to 3 cm into the vagina and the caudal tip extending to a point approximately 2 cm above the anus.

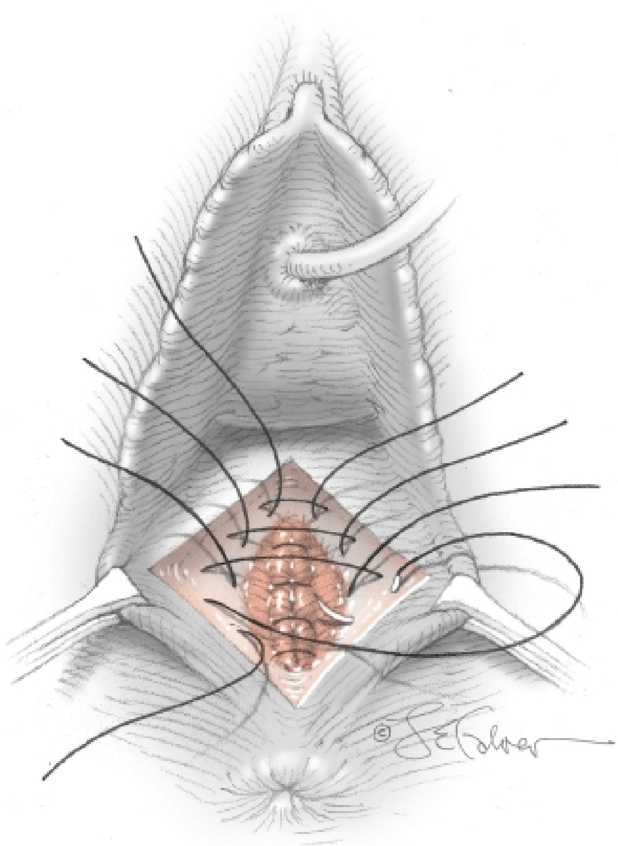
4. **Removal of Skin and Mucosa.** For traction, an Allis clamp is placed at the lowermost tip of the diamond. Metzenbaum scissors are use to excise the perineal skin and vaginal mucosa within the diamond from the underlying tissue. During dissection, the scissor tips are held parallel to the vaginal tissue.

   Sharp dissection must be performed over the perineal body. This area contains a normal condensation of tissue, and additionally, scarring may be present. As a result, development of good tissue planes may not always be possible. Accordingly, frequent rectal examination during dissection may be required to prevent entry into the rectum.

5. **Suture Placement.** One centimeter distal to the hymeneal ring, a 0-gauge delayed-absorbable suture on a CT-1 needle is used to approximate the perineal muscles. In suturing these muscles, a wide lateral bite is taken, and suture is directed first in an inward-to-outward and then outward-to-inward sequence (Fig. 42-16.1). This suture technique effectively buries knots below the plicated muscles. However, initially, the first suture is held and not tied.

   Downward traction is placed, and a second suture is positioned approximately 1 cm cephalad. A third suture can be placed 1 cm further cephalad to this, if necessary. In a similar fashion, one to two stitches are placed 1 cm apart and caudal to the primary suture. The sutures then are tied progressively beginning with the lowermost. In some cases, a second running layer is placed in the superficial perineal muscles for additional support.

FIGURE 42-16.1



Source: Schorge JO, Schaffer JI, Halvorson LM, Hoffman BL, Bradshaw KD, Cunningham FG: *Williams Gynecology*: http://www.accessmedicine.com

Suture placement.

6. **Vaginal and Perineal Closure.** Starting at the vaginal apex, the vaginal mucosa is closed in a running fashion using 2-0 delayed-absorbable suture (Fig. 42-16.2). The surgeon should be mindful that sutures, when creating a running suture line in the vagina, should be placed close together. If suture bites are placed far apart during mucosal closure, the vagina can be shortened.

   The running suture re-approximates the hymeneal ring and then is brought into the perineal area. The same suture then is used in a running mattress method to reapproximate the subcutaneous tissue to the end of the incision, near the anus. Interrupted stitches of of 3-0 delayed-absorbable suture are used to close the perineal skin.

FIGURE 42-16.2

Wound closure.

Postoperative

Patients are instructed to used twice-daily sitz baths, stool softeners, and high-fiber diets. Constipation must be meticulously avoided. Intercourse is delayed until evaluation at 1 month postoperatively. We have found that perineorrhaphy and posterior repair may be associated with short-term urinary retention. This is believed to result from spasm of the levator ani muscles. Therefore, a voiding trial is recommended postoperatively, with assessment of postvoid residuals (see Chap. 39, Voiding Trials).

42-17 ABDOMINAL SACROCOLPOPEXY

Since its introduction in the early 1960s, abdominal sacrocolpopexy has become a widely accepted transabdominal procedure that suspends the vaginal vault to the sacrum using natural or synthetic grafts (Lane, 1962). This procedure is performed primarily to resuspend a prolapsed vaginal apex. Secondary indications include repair of apical segment descent of the anterior vaginal wall (cystocele) and posterior vaginal wall apical segment descent (enterocele and rectocele). A modification of the procedure, *sacrocolpoperineopexy,* is used to repair perineal descent (Weidner, 1997).

Sacrocolpopexy is one of several primary operations chosen for vaginal apex resuspension because of its ability to maintain normal vaginal anatomy and its durability. Long-term success rates range near 90 percent. It may be used as a primary procedure or alternatively, as a second surgery for patients with recurrences after failure of other prolapse repairs. In addition, it is ideal for those believed to be at high risk for recurrence, for example, those with chronically increased intra-abdominal pressure. Such

candidates may include those with chronic obstructive pulmonary disease or chronic constipation, connective tissue disease, history of recurrent hernia, or obesity. In these women, mesh provides augmentation to the patient's own tissues.

Although the vaginal apex also can be suspended successfully with vaginal approach procedures such as sacrospinous ligament fixation (see Section 42-20, Sacrospinous Ligament Fixation) and uterosacral ligament suspension (see Section 42-19, Vaginal Uterosacral Ligament Suspension), sacrocolpopexy offers distinct advantages. Sacrocolpopexy maintains or lengthens the vagina, in contrast to vaginal approaches, which tend to shorten it. Second, the use of permanent mesh with multiple attachment sites to the vagina has a very low risk of failure. Finally, unlike vaginal approaches, the vaginal apex typically remains mobile, thus possibly lowering the risk for dyspareunia.

Sacrocolpopexy provides durable support over time by attaching the vaginal apex and the anterior and posterior vaginal walls to the anterior longitudinal ligament of the spine at the level of the sacrum. Although grafts of autologous, cadaveric, or synthetic materials may be used, permanent (synthetic) mesh has the best success rate and should be used unless otherwise contraindicated (Culligan, 2005).

Sacrocolpopexy also is performed laparoscopically by skilled laparoscopic surgeons. If the laparoscopic operation is performed in the same manner as the open operation, similar results can be expected.

Preoperative

PATIENT EVALUATION

Prior to sacrocolpopexy, patients with symptoms of urinary incontinence should undergo simple or complex urodynamic testing to determine the need for an anti-incontinence procedure (see Chap. 23, Diagnostic Testing). Similarly, women without incontinence also should undergo testing with reduction of the prolapse to assess whether repair will unmask incontinence.

Prolapse of the vaginal apex often coexists with other sites of prolapse along the vaginal vault. For this reason, a careful preoperative assessment should be performed and concurrent prolapse of the anterior or posterior vaginal walls identified, as described in Chapter 24, Perineal Examination. If necessary, sacrocolpopexy can be performed concurrently with paravaginal defect repair, posterior colporrhaphy, or other prolapse procedures. In addition, a modification of the procedure known as sacrocolpoperineopexy may be performed to correct perineal descent. Beer and Kuhn (2005) found that approximately 70 percent of abdominal sacrocolpopexy procedures were performed with other pelvic reconstructive operations.

With the technique we describe, a concurrent enterocele will be repaired by the colpopexy. For this reason Halban- or Moschcowitz-type enterocele repairs are unnecessary. These two repairs close the cul-de-sac of Douglas but have not been proven to decrease prolapse recurrence and may worsen defecatory dysfunction.

In patients with real or potential stress urinary incontinence, a concurrent anti-incontinence operation is performed. The CARE (Colpopexy After Reduction Efforts) trial found that patients without urinary incontinence symptoms undergoing sacrocolpopexy for prolapse of the anterior vaginal wall to within 1 cm of the hymen developed bothersome urinary incontinence in 24 percent of cases. Only 6 percent of those that had a concurrent Burch procedure developed bothersome incontinence (Brubaker, 2006).

CONSENT

As with any prolapse repair, the most important long-term risk is recurrent prolapse. The individual surgeon should be aware of the recurrence rates quoted in the literature of 10 to 15 percent, as well as his or her own personal recurrence rates. Although vaginal apex prolapse recurrence is infrequent, prolapse of the anterior and posterior vaginal walls is common.

Mesh erosion is another complication, developing in 2 to 5 percent of patients. This may develop soon after surgery or years later. Mesh erosion generally is found at the apex and is more common if sacrocolpopexy is performed concurrently with hysterectomy.

PATIENT PREPARATION

Bowel Preparation

Because of the risk of bowel injury during dissection of the sigmoid colon and rectum, a cleansing evacuation is recommended the evening prior to surgery (see Table 39-10).

Antibiotic Prophylaxis

Although this practice has not been rigorously investigated in randomized trials, antibiotics are given preoperatively to decrease the risk of graft infection as well as other abdominal infections.

Medications

Vaginal estrogen cream use during the 6 to 8 weeks prior to surgery has been recommended routinely. It is believed that estrogen treatment enhances vascularity to promote healing and increase tissue strength. Although this is common practice and seems logical, there are no data to suggest that preoperative vaginal estrogen cream is beneficial.

Intraoperative

INSTRUMENTS AND MATERIALS

The upper vagina and vaginal apex must be elevated and distended with a vaginal stent to allow adequate dissection and delineation of the vaginal wall's fibromuscular layers and mesh placement. The vaginal stent may be a large EEA (end-to-end anastomosis) sizer (see Fig. 42-17.5), which is present in most operating rooms, or a cylindrical lucite rod.

The ideal bridging material for this procedure is permanent, nonantigenic, easily cut and customized, and readily available. Although autologous and cadaveric materials have been used, they are not as effective as synthetic mesh, and their use is discouraged. The ideal mesh has a large pore size to allow host tissue ingrowth, is monofilament to decrease bacterial adherence, and is easily manipulated (see Fig. 24-21).

SURGICAL COMPLICATIONS

Significant hemorrhage can develop during dissection and suture placement at the anterior longitudinal ligament. A thorough knowledge of pelvic anatomy is essential to prevent and manage such hemorrhage. The most common vessels lacerated during sacrocolpopexy are the presacral venous plexus and the middle sacral vessels (see Fig. 38-24). Suturing at S3 or S4 vertebral bodies increases the risk of injury to the presacral venous plexus. In contrast, placement of sutures at S1 or the sacral promontory risks laceration of the middle sacral vessels or the left common iliac vein (Wieslander, 2006). At S1, however the middle sacral vessels are readily visible and can be isolated and avoided easily. Additionally, at S1, the anterior longitudinal ligament is thicker and stronger. Affixing sutures into this thicker portion of the ligament minimizes the risk of suture avulsion. For these reasons, many surgeons currently choose to place sutures at S1 or at the level of the sacral promontory (Nygaard, 2004).

With hemorrhage from these vessels, several steps may be critical to its control. First, pressure is applied immediately and held for several minutes. This may be particularly effective for venous bleeding. Sutures and clips may be useful, but injury of small veins frequently worsens with suturing. Additionally, as vessels retract into the bone, isolation and ligation become difficult. Sterile thumbtacks directed through the lacerated vessels and pushed into the sacrum can effectively compress such vessels. Unfortunately, these tacks are not found routinely in many operating rooms.

Alternatively, various local hemostatic agents have been used to control bleeding refractory to these initial steps (see Table 40-5). Although no studies have compared these agents in urogynecologic procedures, animal and vascular studies have shown FloSeal Matrix (Fusion Medical Technologies, Mountain View, CA) to be very effective (Kheirabadi, 2002; Oz, 2000; Weaver, 2002). Moreover, the granular nature of FloSeal Matrix allows conformation to irregular wounds, which is a distinct advantage in managing hemorrhage typical of sacrocolpopexy.

Surgical Steps

1. **Anesthesia and Patient Positioning.** Following administration of general anesthesia, the patient is positioned supine in Allen stirrups. Correct positioning, as described in Chapter 40, Patient Positioning, with no pressure on the calf or thigh and with the thigh parallel to the ground, will decrease the risk of nerve injury. Moreover, this positioning allows excellent access to the vagina and proper placement of the abdominal self-retaining retractor. The buttocks are positioned at the edge of the table or slightly distal to allow full range of vaginal stent manipulation. The vagina and abdomen are surgically prepared, and a Foley catheter is placed.

2. **Incision.** A vertical or transverse abdominal incision as described in Sections 41-1, Midline Vertical Incision and 41-2, Pfannenstiel Incision may be used. Incision selection is directed by a woman's body habitus and by planned concurrent procedures. A Pfannenstiel incision generally provides adequate access to the sacrum and deep pelvis.

   Prior to skin incision, the sacral promontory should be palpated through the abdominal wall deep to the umbilicus. The incision then is placed at a level that allows access to both vaginal apex and promontory. If a Burch colposuspension, paravaginal defect repair, or other surgery in the space of Retzius is planned, then a Pfannenstiel incision that is positioned closer to the symphysis is preferred.

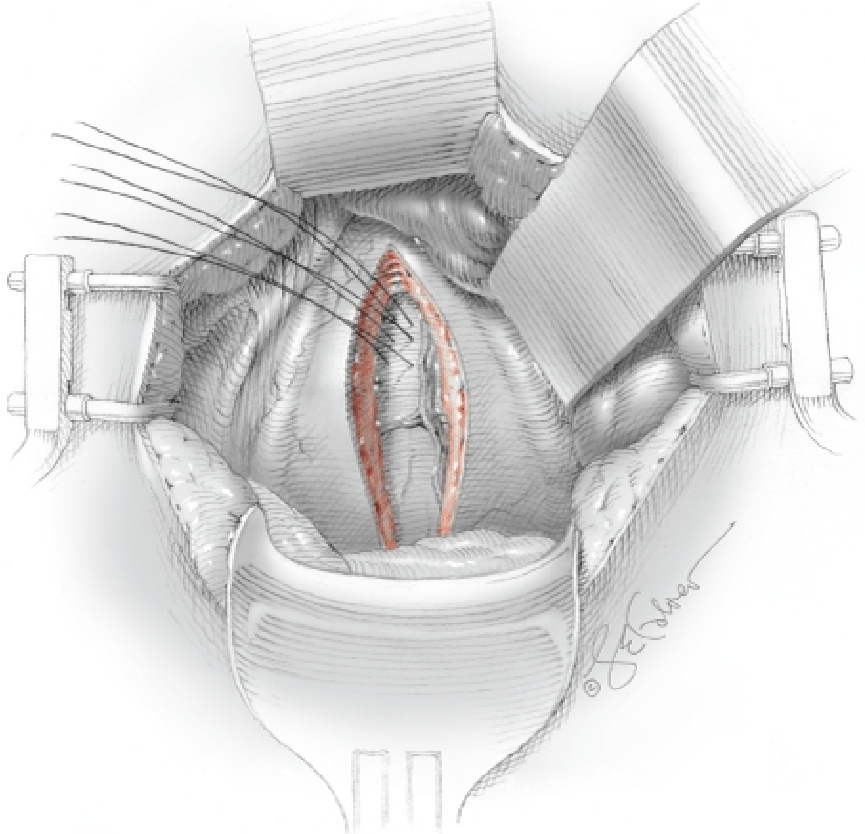
3. **Bowel Packing.** A self-retaining retractor, preferably a Balfour or Bookwalter type, is placed, and the bowel is packed up and out of the pelvis with laparotomy sponges. Bowel packing should attempt to shift the sigmoid colon to the patient's left, thereby allowing access to the sacrum.

4. **Identification of Anatomic Structures.** The aortic bifurcation and iliac vessels are identified, and the middle sacral vessels are palpated ventral to the sacral promontory in the midline. In addition, tracing the course of both ureters aids in avoiding their injury. Specifically, the right ureter is at greater risk than the left during suture placement at the sacrum.

5. **Peritoneal Incision.** The peritoneum overlying the sacral promontory in the midline is elevated with forceps and incised sharply. The incision is extended caudally into the cul-de-sac of Douglas. Closure of this incision at the end of surgery allows the mesh to lie beneath the peritoneum. This may decrease the risk of future adhesion of bowel to mesh.

6. **Placement of Sacral Sutures.** A Kitner sponge is used to gently dissect and remove fat and areolar tissue from the sacrum. Beneath these tissues, the shiny white anterior longitudinal ligament is seen to overlie the bone in the midline. As stated previously, sutures may be placed at S1 through S4. Three sutures of 2-0 permanent material, each double-armed with SH needles, are used. The needle is driven either horizontally or vertically through the anterior longitudinal ligament. Suture placement is determined by each patient's anatomy and ease of placement (Fig. 42-17.1). There is no evidence to suggest that horizontal placement is superior to vertical placement, or vice versa. In some situations, damage to the middle sacral vessels may be avoided by horizontal placement of the sutures around the vessels. Ideally, each suture lies about Â½ cm apart. These sutures, with needles attached, then are held by a hemostat until later in the case.

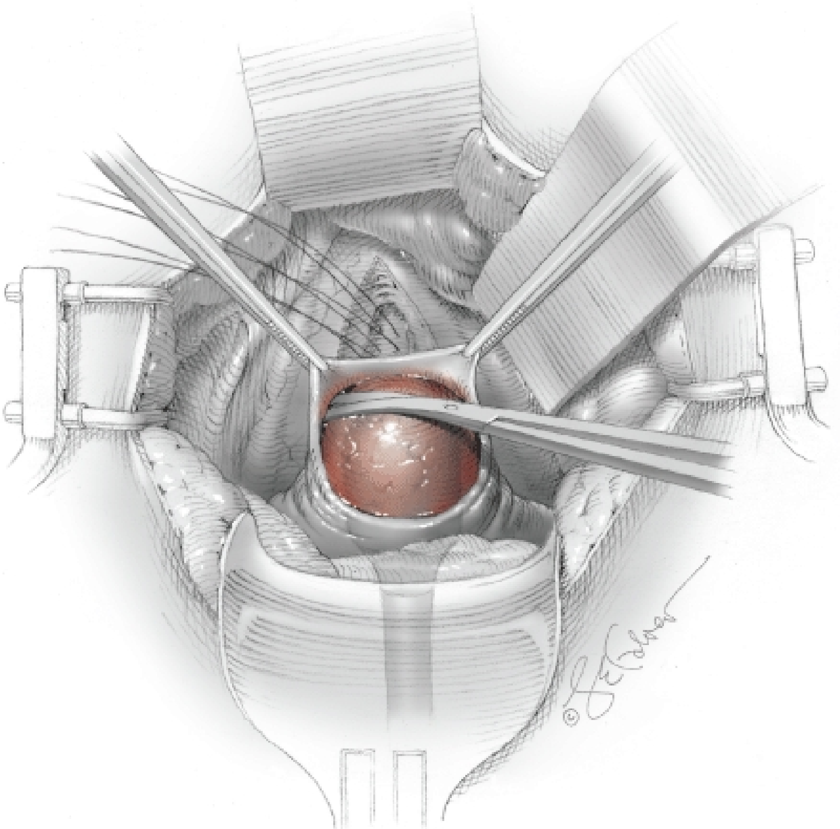
FIGURE 42-17.1



Placement of sacral sutures.

7. **Dissection of the Anterior Vaginal Wall.** A vaginal stent is placed to elevate the vaginal apex, and the peritoneum covering the apex is incised transversely. Sharp and blunt dissection is used to separate the peritoneum and bladder from the anterior vaginal wall (Fig. 42-17.2). This anterior dissection extends approximately 5 to 6 cm caudally to create an extensive surface for mesh fixation. Dissection should progress at a depth above the fibromuscular layer of the vaginal wall. Entry into the proper plane above the fibromuscular layer will decrease the risk of incidental entry into the vagina. Accidental opening of the vaginal wall increases the risk of future mesh erosion secondary to bacterial exposure. If the vaginal wall is opened, it should be irrigated copiously followed by a two-layered imbricating closure with 2-0 or 3-0 delayed-absorbable suture.

FIGURE 42-17.2



Source: Schorge JO, Schaffer JI, Halvorson LM, Hoffman BL, Bradshaw KD, Cunningham FG: *Williams Gynecology*: http://www.accessmedicine.com

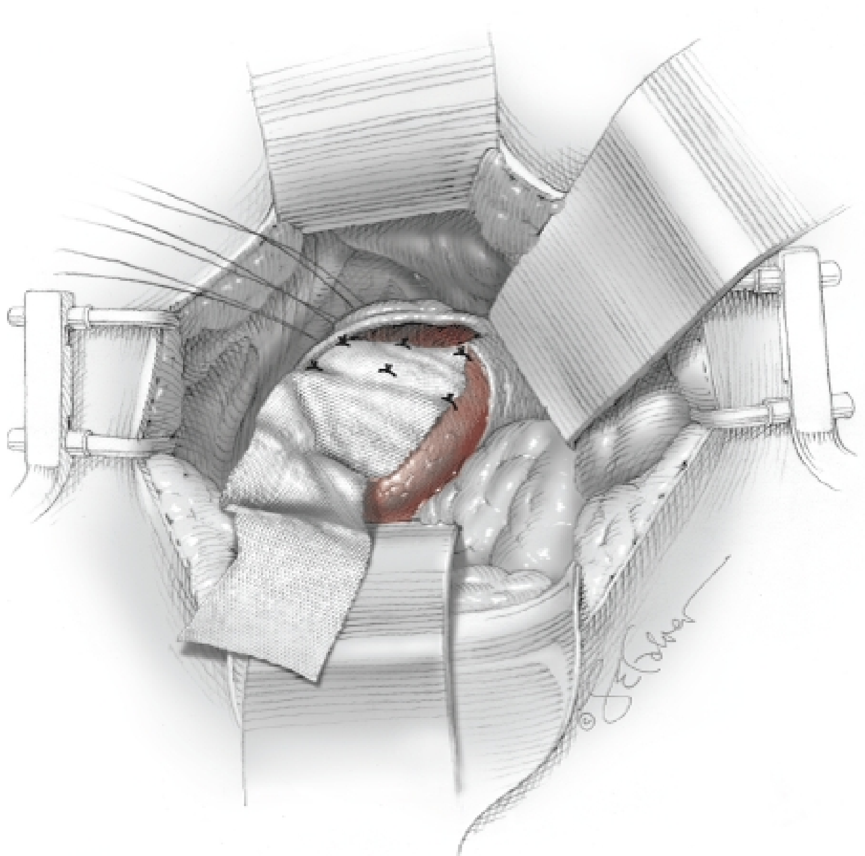
Dissection of the anterior vaginal wall.

8. **Dissection of the Posterior Vaginal Wall.** The vaginal apex is grasped with Allis clamps, pressure is released on the EEA sizer, and the peritoneum covering the posterior vaginal wall then is opened. The rectovaginal space is identified and entered. Blunt dissection further opens this space to the level of the rectal reflection. If sacrocolpoperineopexy is planned, dissection continues beyond the rectal reflection to the level of the perineal body.

   Two rectangular pieces of mesh then are cut to the width of the dissected anterior and posterior vaginal wall surfaces. They are left long to allow fixation to the sacrum later in the procedure.

9. **Posterior Mesh Placement.** For mesh attachment, 2-0 permanent suture is recommended. Six sutures are used at the edges of the mesh to secure it to the vaginal wall's fibromuscular layer. We prefer two rows of three sutures (Fig. 42-17.3). The bottom row is placed at the distal edge of the mesh. Care is taken to avoid placing sutures at the vaginal apex because this is the least vascular region and therefore susceptible to suture and mesh erosion. Attempts are made to avoid penetration of the vaginal epithelium with these sutures. However, if the fibromuscular layer is thin, this will not be possible, and the epithelium is incorporated. These vaginal sutures generally will be epithelialized postoperatively.

FIGURE 42-17.3

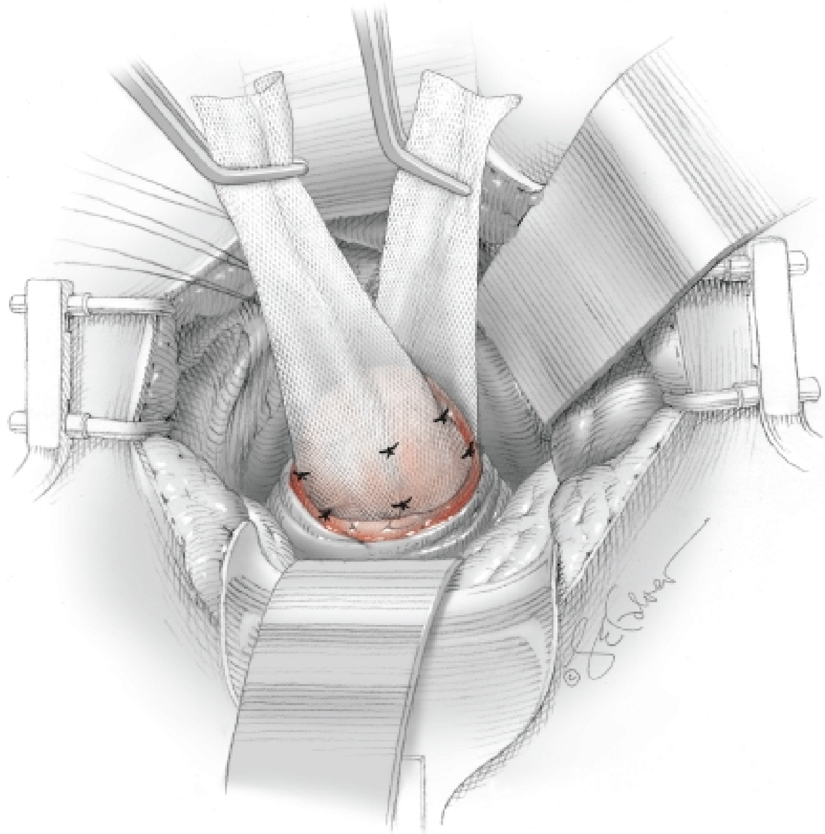


Source: Schorge JO, Schaffer JI, Halvorson LM, Hoffman BL, Bradshaw KD, Cunningham FG: *Williams Gynecology*: http://www.accessmedicine.com

Posterior mesh placement.

10. **Anterior Mesh Placement.** With the vaginal stent serving as a support, mesh is sutured to the anterior vaginal wall in exactly the same fashion as was performed on the posterior vaginal wall (Fig. 42-17.4). In general, the length of the mesh used on the anterior vaginal wall is shorter than that on the posterior vaginal wall.

FIGURE 42-17.4



Source: Schorge JO, Schaffer JI, Halvorson LM, Hoffman BL, Bradshaw KD, Cunningham FG: *Williams Gynecology*: http://www.accessmedicine.com

Anterior and posterior mesh in place.

11. **Passage of Mesh into Peritoneal Tunnel.** After the anterior and posterior meshes are secured, both are passed through the peritoneal tunnel to the sacral sutures.

12. **Vaginal Peritoneal Closure.** The peritoneum is closed over the vaginal apex with 2-0 delayed-absorbable suture in a running fashion.

13. **Mesh Sizing and Attachment to the Sacrum.** The vaginal stent is removed, and digital examination of the vagina is performed. The length of mesh necessary for adequate support is estimated by holding the mesh to the sacrum with the abdominal hand and palpating vaginally. Apical suspension should reduce prolapse of the apex as well as the apical segments of the anterior and posterior vaginal walls. If possible, the mesh should not be placed on tension and then is cut to the appropriate length. The six needles of the three double-armed sacral sutures then are passed through the proximal end of the mesh (Fig. 42-17.5). Each of the three paired sutures then is knotted to secure the mesh to the anterior longitudinal ligament (Fig. 42-17.6).

FIGURE 42-17.5

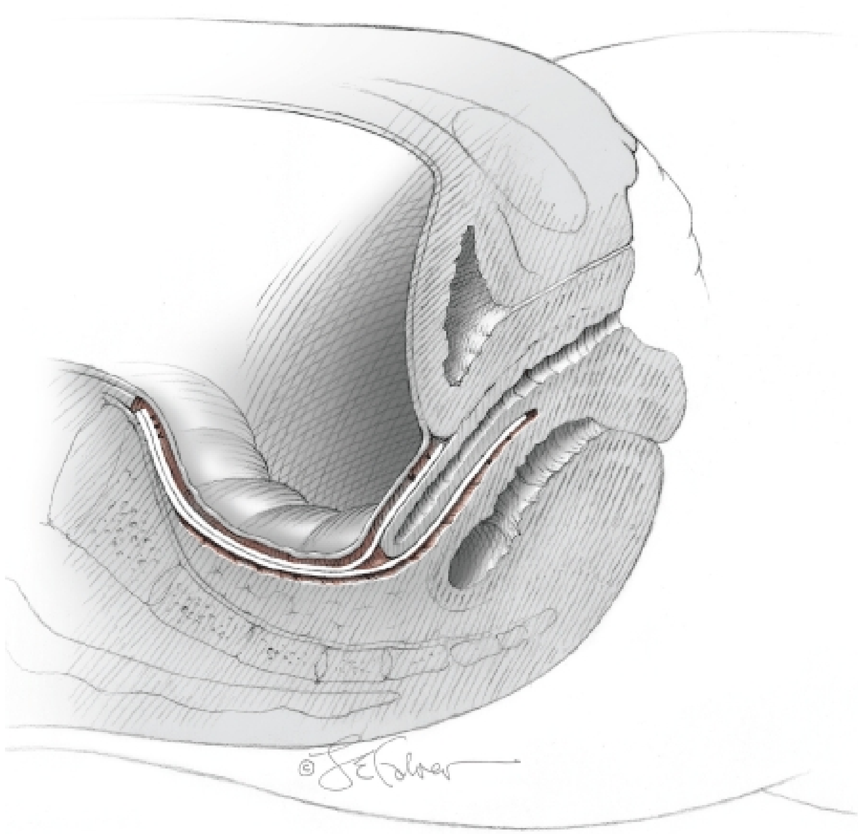
Final mesh placement.

14. **Peritoneal Closure.** The peritoneum is closed over the mesh to the level of the sacral promontory, completely burying the mesh retroperitoneally (Fig. 42-17.7).

FIGURE 42-17.7



Source: Schorge JO, Schaffer JI, Halvorson LM, Hoffman BL, Bradshaw KD, Cunningham FG: *Williams Gynecology*: http://www.accessmedicine.com

Peritoneal closure.

15. **Cystoscopy.** Cystoscopy is performed to ensure ureteral integrity (see Section 42-1, Diagnostic and Operative Cystoscopy and Urethroscopy).

16. **Abdominal Closure.** The abdomen is closed in a standard fashion (see Sections 41-1, Midline Vertical Incision or 41-2, Pfannenstiel Incision).

Postoperative

COMPLICATIONS

Following sacrocolpopexy, the graft material or its attaching sutures can erode through the vaginal muscularis and then the mucosa. This is a frequently cited complication of the procedure but fortunately is uncommon and develops in 2 to 5 percent of cases (Beer, 2005; Nygaard, 2004). Symptoms develop, on average, 14 months following surgery and classically consist of vaginal bleeding and discharge (Kohli, 1998). The diagnosis is straightforward because mesh or sutures can be seen directly on speculum examination.

Of note, recurrent bouts of granulation tissue without visible erosion most likely represent an invisible mesh or suture erosion.

Mesh erosion through the vaginal mucosa may be treated initially with a 6-week course of intravaginal estrogen vaginal cream. For

those in whom epithelium fails to cover the mesh, surgical removal is performed vaginally. The mesh is grasped, placed on tension, and as much mesh as can be identified is resected. The mucosal edges bordering the erosion site are dissected away from the mesh, undermined, and re-approximated. Failure of these wounds to heal should be interpreted as a sign of graft infection, and the graft material should be removed completely either vaginally or abdominally (Mattox, 2004). Similarly, suture erosion of sutures may be managed by removal in the office.

Fortunately, removal of sutures and eroding mesh does not compromise the prolapse repair. In most cases postoperative scarring continues to hold the vaginal apex suspended.

PATIENT CARE

Postoperative in-hospital management is similar to that for other intra-abdominal surgeries. Foley catheter management depends on whether an anti-incontinence procedure was performed. In the absence of such procedures, the catheter can be removed routinely on the first postoperative day. A stool softener should be prescribed as soon as a regular diet is tolerated, and care should be taken to avoid constipation after discharge from the hospital.

At routine postoperative visits, evaluation for prolapse recurrence and mesh or suture erosion should be performed. Symptoms of pelvic floor dysfunction also should be elicited at all postoperative visits. Anatomic success does not always correlate with functional success, and vice versa. Therefore, it is important to continually evaluate the results of surgery based on anatomy as well as symptoms such as urinary incontinence, defecatory dysfunction, pelvic pain, and sexual dysfunction.

42-18 ABDOMINAL UTEROSACRAL LIGAMENT SUSPENSION

Suspension of the vaginal apex can be performed effectively with a variety of vaginal or abdominal surgeries, and success rates approximate 90 percent. Selection of procedure approach is based on a comprehensive assessment of a woman's symptoms and anatomy, as well as surgeon preference. For patients undergoing abdominal surgery, there are two choicesâ€”uterosacral ligament suspension (USLS) and abdominal sacrocolpopexy. Of these two, USLS may be performed in patients with well-defined uterosacral ligaments. In addition, USLS is often preferred for those undergoing hysterectomy because abdominal sacrocolpopexy carries an increased risk of mesh erosion if performed concurrently with hysterectomy (see Sections 42-17, Abdominal Sacrocolpopexy).

During USLS, the uterosacral ligaments are sutured to the anterior and posterior vaginal walls at the vaginal apex. With this suspension, enteroceles are effectively closed. Thus, adjunctive Halban or Moschowitz culdoplasty enterocele repairs are not required.

Preoperative

PATIENT EVALUATION

Prior to USLS, patients with symptoms of urinary incontinence should undergo simple or complex urodynamic testing to determine the need for an anti-incontinence procedure (see Chap. 23, Diagnostic Testing). Patients without incontinence also should undergo testing with reduction of their prolapse to assess whether repair will unmask incontinence.

Prolapse of the vaginal apex often coexists with other sites of prolapse along the vaginal vault. For this reason, a careful preoperative assessment should be performed and concurrent prolapse of the anterior or posterior vaginal walls identified, as described in Chapter 24, Perineal Examination. If necessary, USLS can be performed with paravaginal defect repair, posterior colporrhaphy or other prolapse procedures. In patients with real or potential stress urinary incontinence, a concurrent anti-incontinence operation is performed.

CONSENT

The consent process for USLS should include discussion of general risks associated with abdominal surgery, as well as specific risks associated with the procedure. As with any prolapse repair, the most important long-term risk is recurrence. Thus, surgeons should be aware of recurrence rates quoted in the literature of 10 to 15 percent, as well as their own personal recurrence rates. Although recurrence of vaginal apex prolapse is infrequent, later prolapse of the anterior and posterior vaginal walls is common.

Urinary incontinence also may develop after USLS if an anti-incontinence procedure is not performed. Therefore, preoperative

discussion of bladder function after surgery is essential. Uterosacral ligament suspension does have a potential to shorten and fix the upper vagina. As a result, dyspareunia is a postoperative risk and should be discussed. Additionally, nerve injury with subsequent neuropathy has been reported.

PATIENT PREPARATION

During USLS, an end-to-end anastomoses (EEA) sizer may be placed for rectosigmoid colon manipulation (see Fig. 42-17.5). For this reason, and because of the small but potential risk of bowel injury, bowel preparation is recommended (see Table 39-10). Additionally, antibiotic prophylaxis is provided prior to surgery (see Table 39-7).

Intraoperative

Surgical Steps

1. **Anesthesia and Patient Positioning.** This inpatient procedure is performed under general or regional anesthesia. The patient's legs are placed into Allen stirrups and positioned in a low lithotomy position with the thighs parallel to the ground (see Fig. 40-6).The vagina and abdomen are surgically prepared, and Foley catheter is placed.

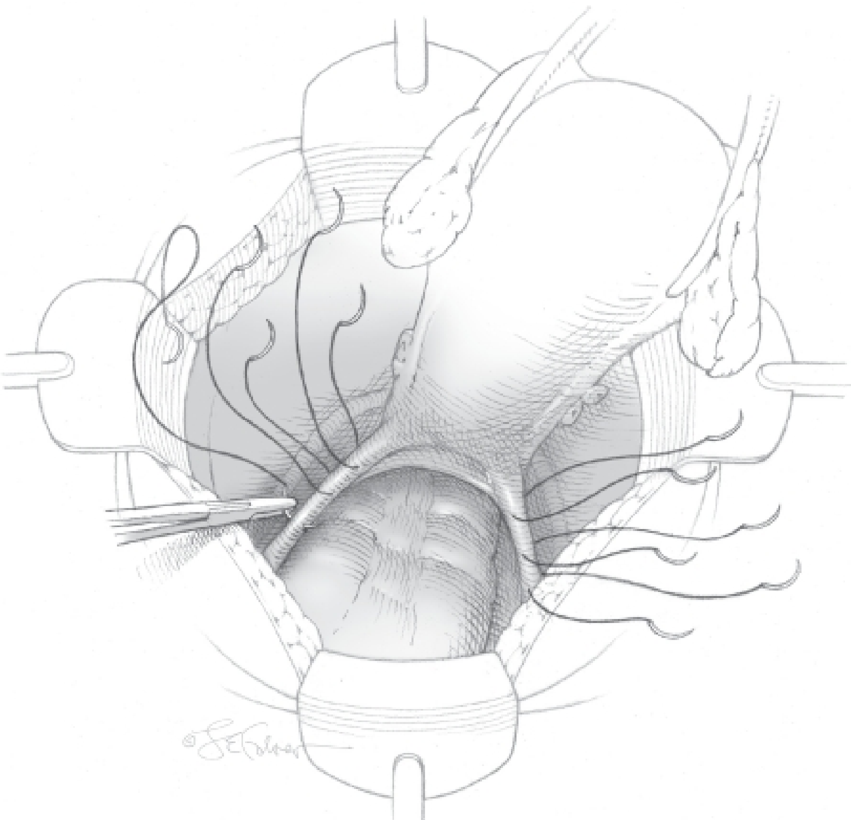
2. **Incision.** This surgery can be performed through a vertical low transverse or Pfannenstiel incision. After the abdomen is opened, a self-retaining retractor is placed and the bowel is packed from the operative field. In most cases, if hysterectomy is planned, then USLS is performed at completion of the abdominal hysterectomy.

3. **Identification of the Ureters.** The ureters are identified bilaterally because of an increased risk of ureteral injury while suturing the uterosacral ligaments.

4. **Identification of Uterosacral Ligaments.** Prior to beginning the hysterectomy, the surgeon should identify the uterosacral ligaments by applying contralateral upward traction to the uterine fundus (Fig. 42-18.1). With this technique, the uterosacral ligaments are placed on stretch and can be identified medial and posterior to the ischial spines.

   Three double-armed sutures of 2-0 permanent suture are placed 1 cm apart in each uterosacral ligament and held (Fig. 42-18.1). This is the step of greatest risk to the ureters. However, it should be emphasized that if sutures are placed medial and posterior to the ischial spines, the ureters will not be in jeopardy. For this reason, an EES sizer may be placed rectally to identify the lateral rectal wall and aid in medial placement of the sutures.

FIGURE 42-18.1



Source: Schorge JO, Schaffer JI, Halvorson LM, Hoffman BL, Bradshaw KD, Cunningham FG: *Williams Gynecology*: http://www.accessmedicine.com

Uterosacral ligaments suture placement.

5. **Hysterectomy.** If hysterectomy is planned, it is now completed, but the cuff is left open. A purse-string suture of 2-0 delayed-absorbable suture is placed 1.5 cm from the edge of the cuff in the vaginal epithelium to close the vaginal apex. This step will prevent many cases of erosion of permanent USLS sutures through the vaginal epithelium.

6. **Suture Placement.** Six sutures are placed equidistant along the horizontal length of the vaginal cuff (Fig. 42-18.2). These sutures are place through the vaginal wall's fibromuscular layer above the prior purse-string. From both sides, the most cephalad sutures are placed through the horizontal midpoint of the vaginal cuff. One arm of the each suture is placed through the posterior fibromuscular layer of the vaginal wall, whereas the other arm sutures the anterior wall. The middle sutures (sutures 2 and 5) are placed next in a similar fashion. Lastly, the angle sutures (sutures 1 and 6) are placed at the cuff angles through the fibromuscular layers of the anterior and posterior vaginal walls.

   At this point, knots are secured starting with most medial sutures (sutures 3 and 4) and ending with the most lateral (sutures 1 and 6). This suturing order may prevent suture bridges in the lateral sutures. Care must be taken to firmly secure all knots and to confirm that the vaginal wall is directly approximated to the uterosacral ligaments (Fig. 42-18.3).

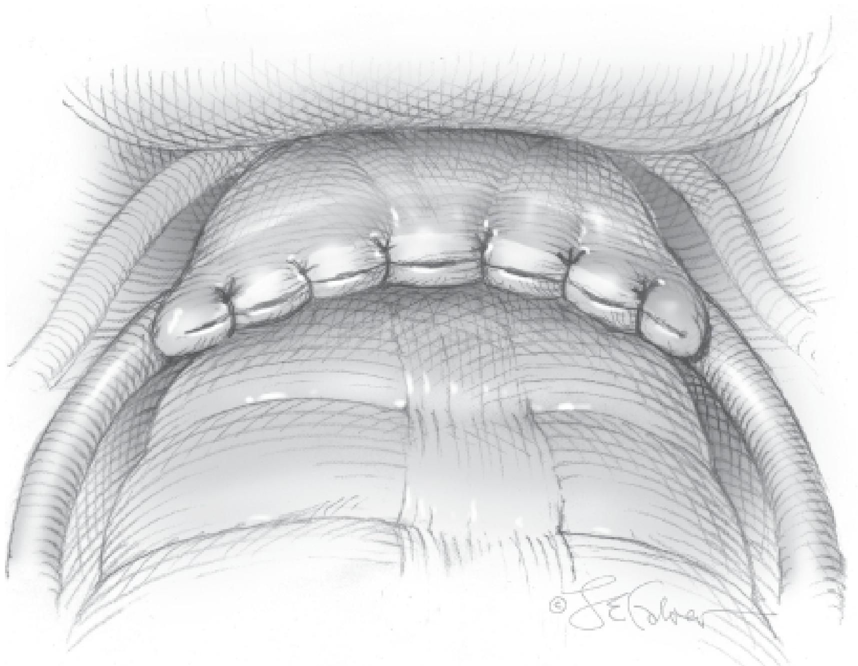
Vaginal cuff suture placement.

FIGURE 42-18.3



Source: Schorge JO, Schaffer JI, Halvorson LM, Hoffman BL, Bradshaw KD, Cunningham FG: *Williams Gynecology*: http://www.accessmedicine.com

All sutures secured.

7. **Cystoscopy.** Cystoscopy is performed following intravenous administration of indigo carmine to document ureteral patency. After cystoscopy, vaginal examination may be performed to assess the need for addition prolapse repair of the anterior and posterior vaginal walls.

8. **Incision Closure.** The abdomen is closed in a standard fashion (see Sections 41-1, Midline Vertical Incision and 41-2, Pfannenstiel Incision).

9. **Concurrent Procedures.** If necessary, prior to incision closure, a paravaginal defect repair (see Section 42-14, Abdominal Paravaginal Defect Repair) or abdominal anti-incontinence surgery may be performed. If posterior colporrhaphy or vaginal anti-incontinence surgery is required, these will follow incision closure.

Postoperative

Following USLS, postoperative care follows that for any major abdominal surgery. Hospitalization typically varies from 2 to 4 days, and return of normal bowel function and febrile morbidity usually dictates this course. Postoperative activity in general can be individualized, although intercourse usually is delayed until after assessment of the vaginal cuff at 4 to 6 weeks following surgery. Catheter maintenance will vary and depends on whether or not anti-incontinence procedures were performed.

Suture erosion with granulation tissue can be a short- or long-term complication. As discussed in Sections 42-17, Abdominal Sacrocolpopexy, patients will present with either an asymptomatic permanent suture seen at the vaginal apex or granulation tissue. Generally, these sutures can be removed in the office. However, if sutures are asymptomatic and difficult to remove, they may remain.

42-19 VAGINAL UTEROSACRAL LIGAMENT SUSPENSION

Vaginal uterosacral ligament suspension (USLS), also called *high uterosacral ligament vault suspension,* is a popular approach to

vaginal apex suspension for women with symptomatic prolapse. In addition, this procedure is effective for repair of apical enteroceles.

During vaginal USLS, anterior and posterior aspects of the vaginal apex are attached to the uterosacral ligaments. As a result, continuity of the posterior and anterior vaginal walls is re-established, and the apex is resuspended.

Apical prolapse commonly develops concurrently with anterior and posterior compartment prolapse. Accordingly, vaginal USLS often is performed in conjunction with other surgeries to correct these defects, such as vaginal hysterectomy, anterior and posterior colporrhaphy, anti-incontinence procedures, and perineorrhaphy.

Preoperative

PATIENT EVALUATION

Prior to this procedure, patients with symptoms of urinary incontinence should undergo simple or complex urodynamic testing to determine the need for an anti-incontinence procedure (see Chap. 23, Diagnostic Testing). Patients without incontinence also should undergo testing with reduction of the prolapse to assess whether suspension of the apex will unmask incontinence. In patients with real or potential stress urinary incontinence, a concurrent anti-incontinence operation is performed.

Prolapse of the vaginal apex often coexists with other sites of prolapse along the vaginal vault. For this reason, a careful preoperative assessment should be performed, as described in Chapter 24, Perineal Examination. If identified, prolapse of the anterior or posterior vaginal walls can be repaired as needed concurrently with USLS.

CONSENT

The consenting process for USLS should include discussion of general risks associated with vaginal surgeries, as well as specific risks associated with the procedure. As with any prolapse repair, the most important long-term risk is recurrent prolapse. Although recurrence of vaginal apex prolapse is infrequent, prolapse of the anterior and posterior vaginal walls is common.

Urinary incontinence also may develop after USLS if an anti-incontinence procedure is not performed. Therefore, preoperative discussion of bladder function after surgery is essential. In addition, uterosacral ligament suspension does have a potential to shorten and fix the upper vagina. Therefore, women should be aware of the potential for postoperative dyspareunia. Additionally, nerve injury and subsequent neuropathy has been reported after USLS and should be discussed.

The ureters are at risk during placement of uterosacral ligament suspension sutures. In the literature, the risk varies and in some series has been reported in up to 25 percent of patients. This complication appears to be related to surgeon experience. Knowledge of anatomy and correct suture placement should minimize this risk.

Permanent sutures are recommended for apical suspension. As a result, suture erosion and nonhealing granulation tissue can develop frequently. Therefore, efforts should be made to avoid suturing through the vagina epithelium.

PATIENT PREPARATION

Bowel preparation and evacuation of the rectum are recommended and are administered the evening prior to surgery (see Table 39-10). In addition, antibiotic prophylaxis is provided prior to surgery.

Intraoperative

Surgical Steps

1. **Anesthesia and Patient Positioning.** Vaginal USLS typically is performed under general or regional anesthesia. The patient is placed in dorsal lithotomy position using candy-cane stirrups. Examination under anesthesia is performed to assess degree of prolapse and confirm the need for surgeries planned. The vagina and abdomen are surgically prepared, and a Foley catheter is placed.

2. **Incision.** The initial incision can be made in a variety of ways. If in the context of vaginal hysterectomy, the vaginal cuff is already open, and uterosacral ligaments are simply identified. However, if the procedure is performed in a woman who previously has undergone hysterectomy, then a vaginal incision can be created in one of two ways. First, a midline incision

may be made in the posterior vaginal wall beginning at the perineum, and dissection proceeds cephalad to the vaginal apex. With this technique, vaginal epithelium is dissected off the vaginal wall. An enterocele sac is identified and entered.

Alternatively, an elliptical incision can be made directly over the entercoele sac at the vaginal apex. The vaginal epithelium is excised in this region, and the enterocele sac is identified and entered.

3. **Packing and Retraction.** A key step of this procedure requires that bowel must be adequately packed away so that high uterosacral sutures can be placed without bowel injury. Several moist laparotomy sponges are placed in the cul-de-sac of Douglas and hollow of the sacrum to elevate bowel from the operative field.

   Additionally, two Breisky-Navratil retractors are positioned (see Fig. 40-20). One reflects the rectum to the contralateral side of the ligament being sutured. A second is used to reflect remaining bowel. At times, a third may be necessary to clear the field adequately.

4. **Identification of Uterosacral Ligaments.** Initially, the ischial spines are palpated, and the uterosacral ligaments are found medial and posterior to the spines and lateral to the rectum. Additionally, Allis clamps may be placed on the posterior vaginal wall at the apex. If traction is applied, uterosacral ligaments become taut and are identified more easily by their cord-like texture.

5. **Placement of Sutures in the Uterosacral Ligament.** Beginning at the level of the ischial spines and progressing cephalad, a surgeon places three double-armed 2-0 permanent sutures approximately 1 cm apart in each uterosacral ligament (Figs. 42-19.1 and 42-19.2). Following the normal path of these ligaments, the most caudal sutures will be most medial.

   To avoid ureteral injury, it is of vital importance that sutures be placed medial and posterior to the ischial spines. In addition, ureteral injury is averted by directing needles medially during suturing. Although this will place sutures near the lateral border of the rectum, bowel injury is avoided by retraction with a Breisky-Navratil retractor.

   In some instances, uterosacral ligaments are attenuated and difficult to identify distinctly. In these circumstances, suturing may proceed by placing stitches in the expected anatomic area for these ligaments.

   Hematomas may form occasionally following inadvertent laceration of the lateral rectal veins. Should this occur, application of pressure with a sponge stick typically will control bleeding.

Source: Schorge JO, Schaffer JI, Halvorson LM, Hoffman BL, Bradshaw KD, Cunningham FG: *Williams Gynecology*: http://www.accessmedicine.com

Lateral view of sutures placed into the left uterosacral ligament.

6. **Cystoscopy.** After all six stitches are placed and tied, 1/2 to 1 ampule of indigo carmine is administered intravenously. Cystoscopy is performed to exclude ureteral injury prior to proceeding with the remaining surgical steps.

7. **Placement of Sutures in the Vaginal Wall.** The most distal suspensory suture on each side is sown to the most lateral portion of the anterior and posterior fibromuscular layers at the corner of the vaginal apices. The suture cephalad to this first one is placed more medially, through the vaginal wall. Finally, the most cephalad suture is placed in the midline of the anterior and posterior fibromuscular layers. Tangling of sutures is common. Thus, sutures may be tagged, numbered, and attached to surgical drapes.

   Vaginal packing is removed, and sutures are tied. The most medial sutures are tied first. As knots are secured, the vaginal walls should be brought into immediate contact with the uterosacral ligaments to avoid bow-stringing, which can lead to bowel obstruction.

8. **Closure of the Vaginal Cuff.** The vaginal cuff is reapproximated in a running fashion with 2-0 delayed-absorbable suture.

Postoperative

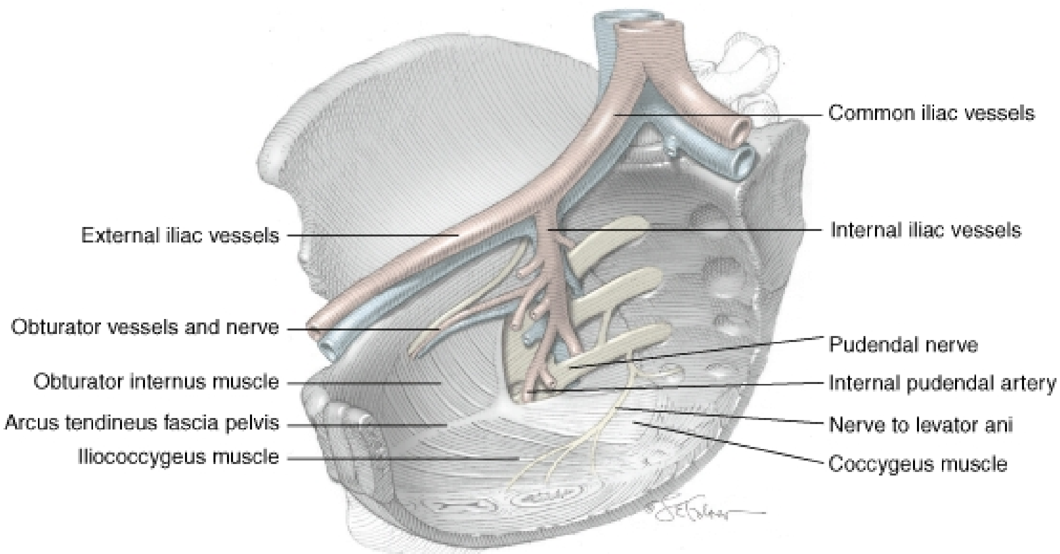
Following USLS, postoperative care follows that for any vaginal surgery. Postoperative activity in general can be individualized, although intercourse usually is delayed until after assessment of the vaginal cuff at 4 to 6 weeks following surgery. Catheter maintenance will depend on whether or not anti-incontinence procedures were performed.

42-20 SACROSPINOUS LIGAMENT FIXATION

Prolapse of the vaginal apex may be corrected by several procedures. One vaginal approach, termed *sacrospinous ligament fixation,* uses the strength of the sacrospinous ligament to resuspend the apex. Stretching from the ischial spine to the lateral surface of the sacrum's inner hollow, this ligament is a tough, fibrous aponeurosis that lies within the body of the coccygeus muscle (Fig. 42-20.1). The great size and tensile strength of this ligament allow it to serve as an excellent support for suspensory surgery.

Although effective in correcting apical prolapse, sacrospinous ligament fixation compares less favorably with abdominal sacrocolpopexy (Benson, 1996; Maher, 2004). However, sacrospinous ligament fixation averts abdominal surgery and is associated with shorter operating times and quicker recovery. For these reasons, it often provides a superior choice for women with other significant health problems. Additionally, the vaginal approach allows other concurrent support defects to be repaired vaginally at the same time as fixation. Compared with other vaginal approaches for vault suspension, success rates are comparable (Maher, 2001).

FIGURE 42-20.1



Source: Schorge JO, Schaffer JI, Halvorson LM, Hoffman BL, Bradshaw KD, Cunningham FG: *Williams Gynecology*: http://www.accessmedicine.com

Sacrospinous ligament and surrounding pelvic anatomy.

Preoperative

PATIENT EVALUATION

Prior to sacrospinous ligament fixation, women with symptoms of urinary incontinence should undergo urodynamic testing to determine the need for an adjunctive anti-incontinence procedure (see Chap. 23, Diagnostic Testing). Patients without incontinence also should undergo testing with reduction of the prolapse to assess whether suspension of the apex will unmask incontinence. In women with real or potential stress urinary incontinence, a concurrent anti-incontinence operation is indicated.

Prolapse of the vaginal apex often develops with prolapse at other sites along the vaginal vault. Accordingly, careful preoperative assessment should be performed, as described in Chapter 24, Perineal Examination. If identified, prolapse of the anterior or posterior vaginal walls can be repaired as needed concurrently with sacrospinous ligament fixation.

CONSENT

For most women, sacrospinous ligament fixation is effective in preventing recurrent apical prolapse, and success rates range from 70 to nearly 100 percent (Cruikshank, 2003; Lantzsch, 2001; Maher, 2004). The procedure is safe and associated with low rates of

serious complications. Significant hemorrhage requiring transfusion is uncommon and typically results from injury to the pudendal, inferior gluteal, or inferior rectal vessels. Rates of long-term nerve injury similarly are low, and injury typically involves the pudendal or inferior gluteal nerves (Sagsoz, 2002). Rarely, life-threatening infections such as necrotizing fasciitis and ischiorectal fossa abscess may develop (Hibner, 2005; Silva-Filho, 2005).

As with other pelvic reconstructive surgeries, new pelvic support defects may follow sacrospinous fixation, and rates for development of any support defect range from 15 to 40 percent (Paraiso, 1996; Shull, 1992). During fixation, the vagina's long axis is redirected posteriorly. As this axis is lowered, the anterior compartment of the pelvis widens and lies vulnerable to increased intra-abdominal pressures. Accordingly, anterior compartment defects (cystoceles) develop postoperatively in 10 to 40 percent of patients (Lantzsch, 2001; Paraiso, 1996). As a result, increased rates of stress urinary incontinence also may be noted.

Concern is often expressed regarding shortening of the functional vaginal length by this procedure, and postoperative lengths approximate 8 cm (Given, 1993). Despite a resulting shorter vaginal length when compared with an abdominal approach for suspension, de novo dyspareunia is infrequent. Indeed, for many women, replacement of the vagina to a more anatomic location leads to improved satisfaction with intercourse following surgery (Maher, 2004).

PATIENT PREPARATION

The risk of intraoperative rectal injury is not uncommon with sacrospinous ligament fixation. For this reason, bowel preparation, is performed the evening prior to surgery (see Table 39-10).

As with most vaginal surgery, because of the risk posed by the normal vaginal flora for postoperative wound cellulitis and abscess, preoperative antibiotics are warranted. Typical agents include first- or second-generation cephalosporins.

Intraoperative

SURGICAL INSTUMENTS

Placement of sutures into the sacrospinous ligament can be performed with a variety of ligature carriers, including the Dechamps ligature carrier, Miya hook, Capio ligature carrier (Boston Scientific, Boston, MA), and the EndoStitch (United States Surgical, Norwalk, CT). Using the Deschamps ligature carrier, the surgeon threads the suture through an eye at the needle-shaped tip of the carrier. Arcs and curves constructed into the instrument aid of suture placement into the ligament. Disadvantages to this device, however, include the relative thickness of the needle tip, which can add difficulty in perforating the ligament. Alternatively, Miyazaki (1987) described 74 cases using the Miya hook. This device aids in passage through the ligament. However, there is less control of the needle and suture because the device has moving parts. These first two offer additional cost advantages because they are reusable. With adequate exposure, another reusable device that can be used easily is a long needle driver.

Alternatively, disposable devices have become popular, in particular, the Capio ligature carrier (Boston Scientific, Natick, MA). This device is easier to manipulate than the Miya hook, and the needle is well controlled at all times.

Surgical Steps

1. **Anesthesia and Patient Positioning.** After general anesthesia has been administered, the patient is placed in dorsal lithotomy position, the vagina is surgically prepared, and a Foley catheter is placed. Initially, vaginal vault prolapse is reduced to place the vagina in a normal anatomic position. Enterocele or cystocele repairs, if planned, should precede sacrospinous ligament fixation.

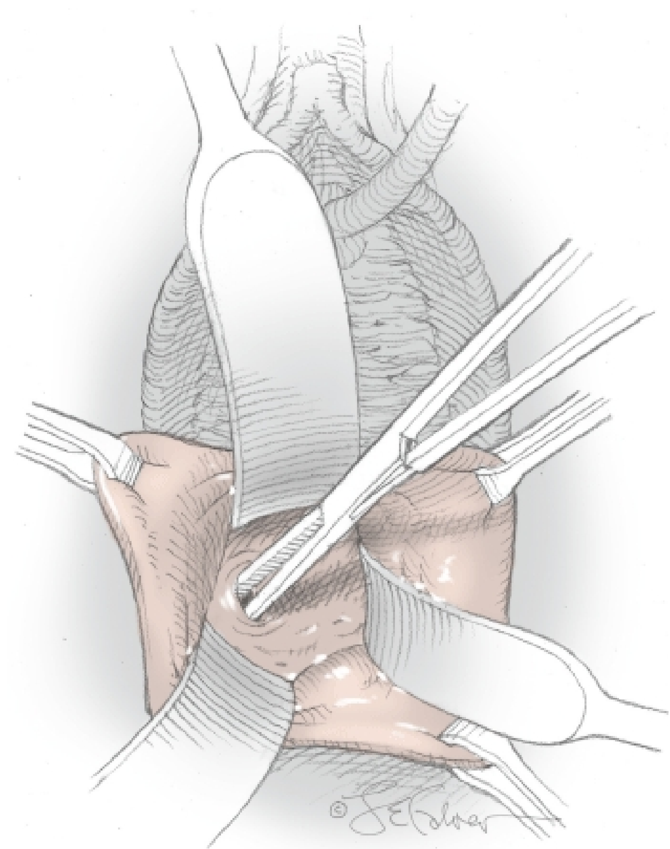
2. **Unilateral or Bilateral Fixation.** Although the vaginal apex may be attached to either one or both sacrospinous ligaments, in most instances, unilateral fixation gives sufficient support. The right ligament is preferred because most surgeons are right handed. Additionally, fixation to the right side avoids anatomic difficulties posed by the rectum.

   Alternatively, bilateral fixation has been advocated as a method to maintain the vaginal apex in a midline plane and to provide superior durability because of additional support given by two ligaments (Cespedes, 2000). Clear benefits to bilateral compared with unilateral fixation have not, however, been evaluated in clinical trials, and greater rates of postoperative anterior compartment prolapse have been noted following bilateral fixation (Pohl, 1997).

3. **Access to the Sacrospinous Ligament.** The sacrospinous ligament is accessed through the pararectal space. Entering the pararectal space permits close proximity to the ligament with minimal dissection.

4. **Entry into Pararectal Space.** Using a pararectal approach, the surgeon sharply incises the posterior vaginal wall and separates it from the underlying rectum, as described in Section 42-15, Posterior Colporrhaphy. These steps reveal the perirectal fascia, and the rectal pillars are seen on either side of the rectum (Fig. 42-20.2). The right rectal pillar is entered sharply by placing and opening a hemostat at the level of the ischial spine. This blunt dissection permits entry into the pararectal space.

FIGURE 42-20.2



Source: Schorge JO, Schaffer JI, Halvorson LM, Hoffman BL, Bradshaw KD, Cunningham FG: *Williams Gynecology*: http://www.accessmedicine.com

Entry into pararectal space.

5. **Retractor Positioning.** Breisky-Navratil retractors are positioned within the pararectal space (see Fig. 40-20). The first, positioned anteriorly, lifts pelvic contents away from the surgical site. The second is place to the patient's left and retracts the rectum. The last is held inferiorly and parallel to the ligament.

6. **Ligament Dissection.** After entering the right pararectal space, the ischial spine is located digitally, and the path of the sacrospinous ligament is traced medially. Blunt dissection with fingertips removes loose adventitial tissue overlying the midportion of the ligament.

During dissection within the pararectal space or retraction of the rectum, vessels in the area may be lacerated and most commonly include branches of the inferior rectal vessels. Hemorrhage in this area is often best managed with packing a sponge into the area and holding pressure.

7. **Ligature Placement.** Following dissection, the ligament is grasped with a Babcock clamp at a spot approximately 2.5 cm medial to the ischial spine. This transforms the flat ligament into a thicker, more rounded structure and often allows the lateral retractor to be removed for greater visualization and mobility of the ligature carrier.

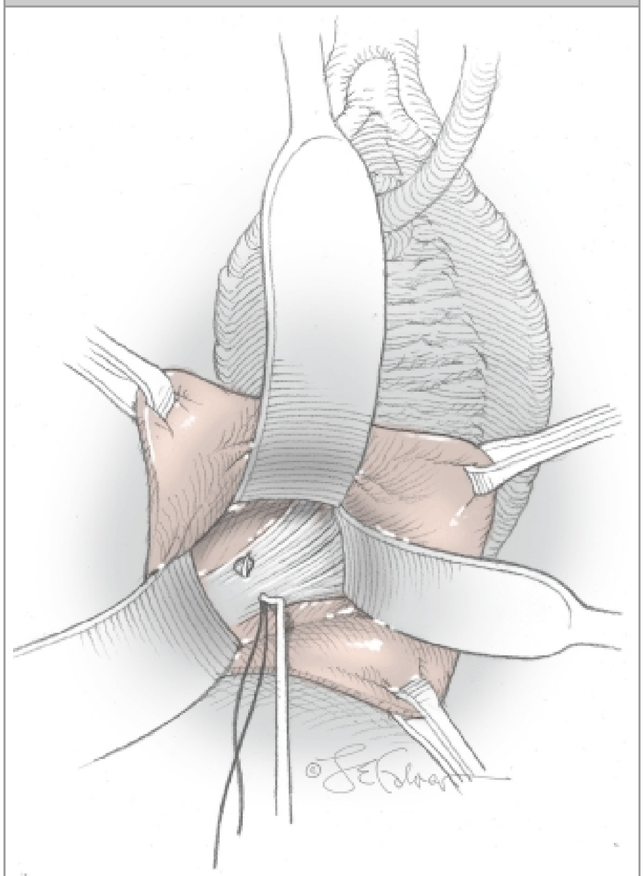
   A ligature carrier is loaded with 0-gauge permanent suture. Although erosion of sutures through the vaginal apex postoperatively has been noted, use of permanent sutures increases repair durability (Chapin, 1997). In addition, use of monofilament sutures to lower infection risks in this procedure has been advocated (Hibner, 2005).

   The pudendal and inferior gluteal vessels and nerves lie behind the sacrospinous ligament and may be injured during sacrospinous ligament fixation. For this reason, sutures should be placed 2.5 to 3 cm medial to the ischial spine and are not placed completely through the entire thickness of the ligament (Sagsoz, 2002; Verdeja, 1995).

   If a vessel is lacerated and immediate isolation and ligation are not possible, the area of hemorrhage may be packed with laparotomy sponges and pressure held for several minutes. As sponges then are removed gradually, a site of laceration can be identified and clipped with a vascular clip or ligated.

   A ligature carrier is held in the surgeon's right hand, and the tip of the driver is placed toward the inferior edge of the ligament (Fig. 42-20.3). The tip then pierces the ligament with a clockwise motion of the carrier.

FIGURE 42-20.3



Source: Schorge JO, Schaffer JI, Halvorson LM, Hoffman BL, Bradshaw KD, Cunningham FG: *Williams Gynecology*: http://www.accessmedicine.com

Ligature placement.

8. **Vaginal Apex Suturing.** The suture loop is snagged with a nerve hook and pulled into the vagina. The loop is cut, thereby leaving two separate sutures within the ligament. This allows placement of two sutures with only one carrier pass and thus minimizes adjacent tissue injury. Two pulley stitches then are placed in the vaginal apex (Fig. 42-20.4).

   With the Michigan modification of this procedure, two sutures are placed through the ligament, allowing for four sutures with two ligament passes (Figs. 42-20.5 and 42-20.6). These sutures then are used to attach the anterior and posterior vaginal walls to the sacrospinous ligament.

FIGURE 42-20.4

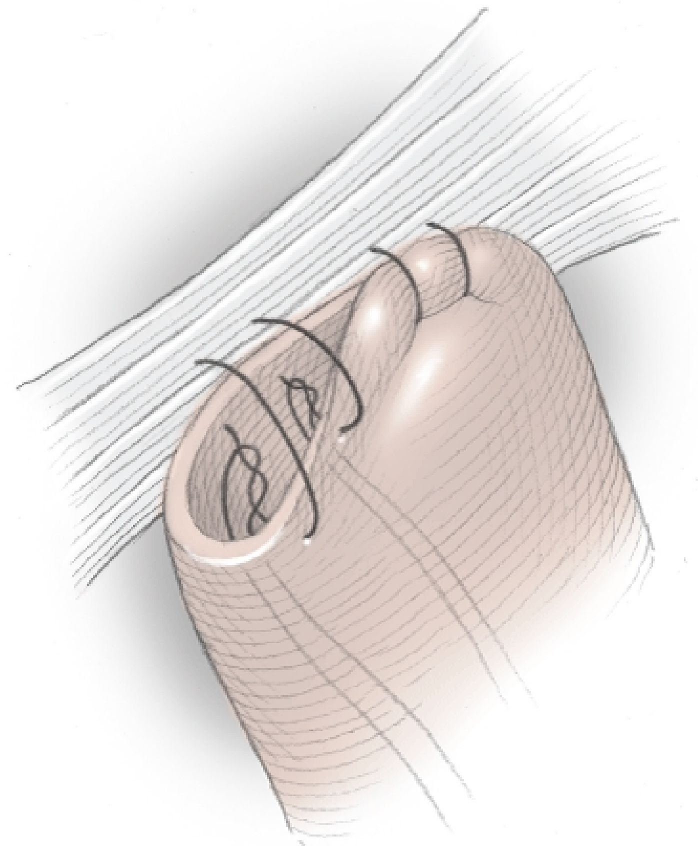
FIGURE 42-20.6



Source: Schorge JO, Schaffer JI, Halvorson LM, Hoffman BL, Bradshaw KD, Cunningham FG: *Williams Gynecology*: http://www.accessmedicine.com

Vaginal apex approximated to ligament.

9. **Closure of Posterior Vaginal Wall and Pararectal Space.** The proximal posterior vaginal wall is reapproximated with a running closure using 2-0 delayed-absorbable suture. The pararectal space then is closed similarly.

10. **Vault Resuspension.** The pulley stitches then are tightened, bringing the vaginal apex directly to the ligament. The remainder of the vaginal wall then is closed in a running fashion using 2-0 delayed-absorbable suture.

Postoperative

Following surgery, patients may ambulate on the first postoperative day, and diet may be advanced as tolerated. Mild buttock pain may follow surgery and resolves typically in days to months. Such neuralgia is common following surgery, and Lantzsch and associates (2001) found a rate of 8 percent in their series. Nonsteroidal anti-inflammatory drugs in this setting may be helpful.

Occasionally, a patient may complain of severe pain and display sensory or motor neurologic symptoms or both (see Chap. 40, Sciatic Nerve). If motor symptoms are present, the chance for nerve entrapment of sciatic nerve or its branches is great. These women should undergo exploration of the pararectal space and removal of entrapping sutures.

42-21 MCCALL CULDOPLASTY

McCall culdoplasty is performed at the time of vaginal hysterectomy to close the cul-de-sac, add support to the posterior vaginal apex, and possibly prevent enterocele formation. The main difference between this procedure and Halban and Moschcowitz

culdoplasty methods lies in its vaginal approach. No data support the superior efficacy of one when these three are compared. Thus, the choice of procedure should be based on the approach planned for hysterectomy and on other concurrent surgeries.

Culdoplasty is suggested to prevent enterocele formation and vaginal vault prolapse. However, if significant vaginal apex prolapse or enterocele is already present, then either sacrospinous ligament fixation or vaginal uterosacral ligament suspension of the vaginal vault is preferred.

Preoperative

PATIENT EVALUATION

McCall culdoplasty generally is performed following vaginal hysterectomy in women with enterocele or preventively in those without. Because the degree of pelvic organ prolapse will dictate the reconstructive surgeries planned, a thorough prolapse evaluation should be performed, as described in Chapter 24, Perineal Examination.

CONSENT

As with any pelvic reconstructive surgery to correct prolapse, the risk of enterocele formation or recurrence should be discussed. Risks of ureteral and bowel injury, although low, should be included in the consenting process.

PATIENT PREPARATION

Postoperative vaginal cuff cellulitis and urinary tract infection may follow hysterectomy, and patients typically receive antibiotic prophylaxis with either a first- or second-generation cephalosporin. Alternatively, clindamycin may be used. The risk of bowel injury is low. However, bowel preparation is recommended prior to surgery to evacuate the rectum and thus decrease contamination should proctotomy occur.

Intraoperative

Surgical Steps

1. **Anesthesia and Patient Positioning.** McCall culdoplasty typically is performed under general anesthesia, although epidural or spinal regional methods may also be appropriate. The patient is placed in a high lithotomy position in candy-cane stirrups. The vagina is surgically prepared, and a Foley catheter is inserted. Vaginal hysterectomy is completed as described in Section 41-20, Vaginal Hysterectomy, but the vaginal cuff is left open for completion of the culdoplasty.

2. **Packing.** After vaginal hysterectomy, a moist pack is placed into the posterior cul-de-sac to prevent descent of bowel or omentum into the operative field.

3. **Identification of Uterosacral Ligaments, Rectum, and Ureters.** The uterosacral ligaments, which were tagged previously during vaginal hysterectomy, are placed on lateral traction to define the course of the ligaments to the pelvic sidewall. Alternatively, Allis clamps can be placed on the posterior vaginal wall and traction applied to identify the uterosacral ligaments. The ureter always lies lateral to the uterosacral ligament, and although it may not be visualized per se, placement of sutures medial to the ligament will avoid ureteral injury. Additionally, rectal examination should delineate the lateral borders of the rectum to avoid needle stick injury to the bowel.

4. **Suture Placement.** The first internal 2-0 permanent suture is placed proximally into one uterosacral ligament, taking care to always direct the needle toward the midline to avoid ureteral injury (Fig. 42-21.1). Subsequent serial bites are placed 1 cm apart across the rectosigmoid colon's serosa to reach and penetrate the opposite ligament. This suture is left untied. Additional caudal rows of sutures are similarly placed 1 cm apart between the uterosacral ligaments, extending caudally toward the vaginal cuff. Depending on the size and depth of the cul-de-sac, the number of rows will vary.

   Following completion of the internal suture rows, one external suture row is placed using 2-0 delayed-absorbable suture and incorporates the posterior vaginal wall. This suture is placed initially through the full thickness of the posterior vaginal wall and into the uterosacral ligament. Progressive left to right bites then are taken serially through the rectosigmoid serosa to reach the opposite uterosacral ligament. Finally, the suture enters the opposite uterosacral ligament and exits through the full vaginal wall thickness to re-enter the vagina (Fig. 42-21.2).

FIGURE 42-21.1

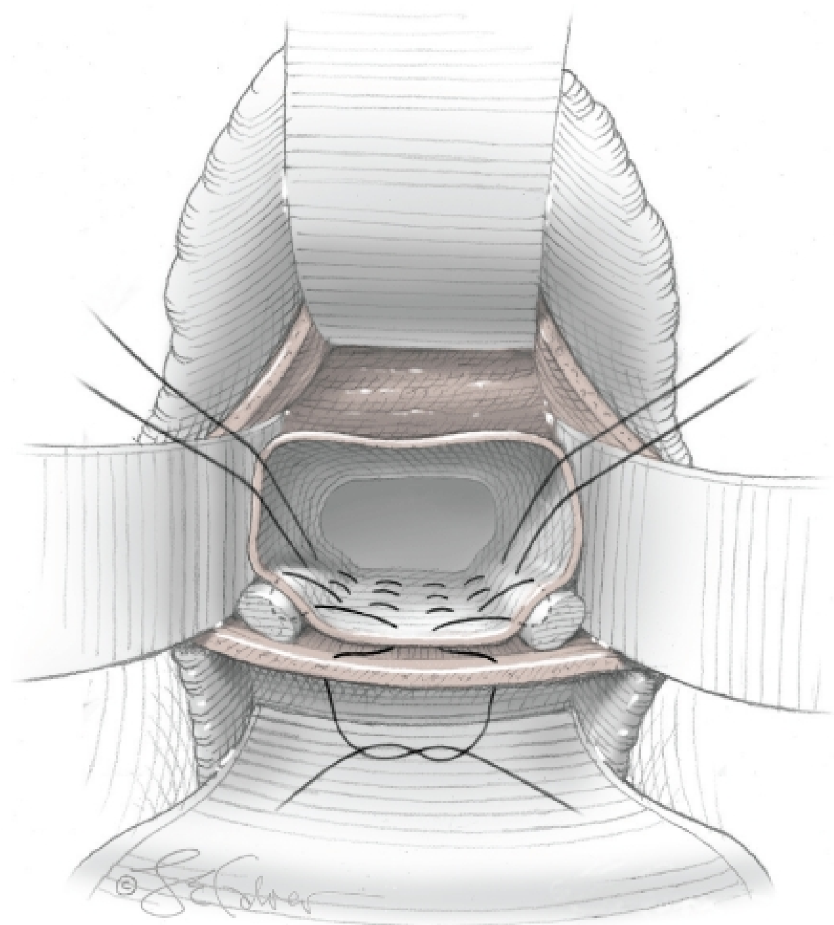
Uterosacral ligament suture placement.

FIGURE 42-21.2



Source: Schorge JO, Schaffer JI, Halvorson LM, Hoffman BL, Bradshaw KD, Cunningham FG: *Williams Gynecology*: http://www.accessmedicine.com

Suture reenters the vagina prior to securing.

5. **Suture Tying.** The sutures are tied sequentially beginning with the most proximal sutures and progressing caudally.

6. **Cystoscopy.** Because of the proximity of suture placement to the ureters, cystoscopy should be considered to document ureteral patency.

7. **Vaginal Cuff Closure.** On completion of McCall culdoplasty, the remaining steps of vaginal hysterectomy will follow, as described in Section 41-20, Vaginal Hysterectomy (Step 11).

Postoperative

Following vaginal hysterectomy and McCall culdoplasty, postoperative care follows that for most vaginal surgeries. Hospitalization typically varies from 1 to 3 days, and return of normal bowel and bladder function usually dictates this course. Postoperative activity in general can be individualized, although intercourse usually is delayed until after the first postoperative visit at 4 weeks to allow inspection of vaginal cuff healing.

42-22 ABDOMINAL CULDOPLASTY PROCEDURES

Culdoplasty techniques are used to obliterate the cul-de sac of Douglas and prevent herniation of small bowel into the vaginal wall. Thus, these procedures traditionally have been thought of as appropriate for repair and prevention of enteroceles. However, evidence-based studies have not borne out these benefits, and current concepts of specific pelvic support defect repair have decreased the popularity of culdoplasty. Nevertheless, this procedure is still performed commonly and may have value when performed in conjunction with other prolapse procedures.

Included in this group are the Moschcowitz and Halban procedures. With these, permanent sutures are used to close the cul-de-sac, and procedures vary based on the orientation of suture placement. Either the Halban or Moschcowitz procedure may be selected, and the decision is based on surgeon's preference and concurrent abdominal or vaginal pathology. No studies have been completed that compare these techniques.

Preoperative

PATIENT EVALUATION

Culdoplasty procedures typically are performed with other prolapse surgeries. Thus, thorough pelvic organ prolapse evaluation should be performed, as described in Chapter 24, Perineal Examination. All sites of prolapse should be considered when planning surgical correction. Depending on the type of prolapse present, urodynamic testing also may be indicated to exclude potential stress urinary incontinence.

CONSENT

As with any pelvic reconstructive surgery to correct prolapse, the risk of enterocele recurrence following abdominal culdoplasty should be discussed. Additionally, risks of ureteral and bowel injury should be included in the consenting process. During Halban and Moschcowitz culdoplasty, the rectosigmoid is plicated to the posterior vaginal wall. Accordingly, defecatory dysfunction and technical difficulty in performing subsequent colonoscopy have been reported following these procedures.

PATIENT PREPARATION

Because of the potential for bowel injury, bowel preparation is performed the evening prior to surgery (see Table 39-10). In addition, antibiotic prophylaxis is administered immediately before surgery.

Intraoperative

Surgical Steps

1. **Anesthesia and Patient Positioning.** Abdominal culdoplasty typically is performed under general anesthesia, although regional techniques may also be used. The patient is positioned in a low lithotomy position with the legs in Allen stirrups and the thighs parallel to the ground. This positioning allows access to the vagina as well as normal abdominal laparotomy exposure. A Foley catheter is placed, and the abdomen and vagina are prepared for surgery.

2. **Surgical Incision.** Either a transverse or a vertical incision may be used for culdoplasty. Incision choice depends on concurrent surgeries planned (see Sections 41-1, Midline Vertical Incision and 41-2, Pfannenstiel Incision). A self-retaining retractor such as an O'Connor-O'Sullivan or Balfour retractor is placed, and concurrent surgeries such as hysterectomy or sacrocolpopexy are performed.

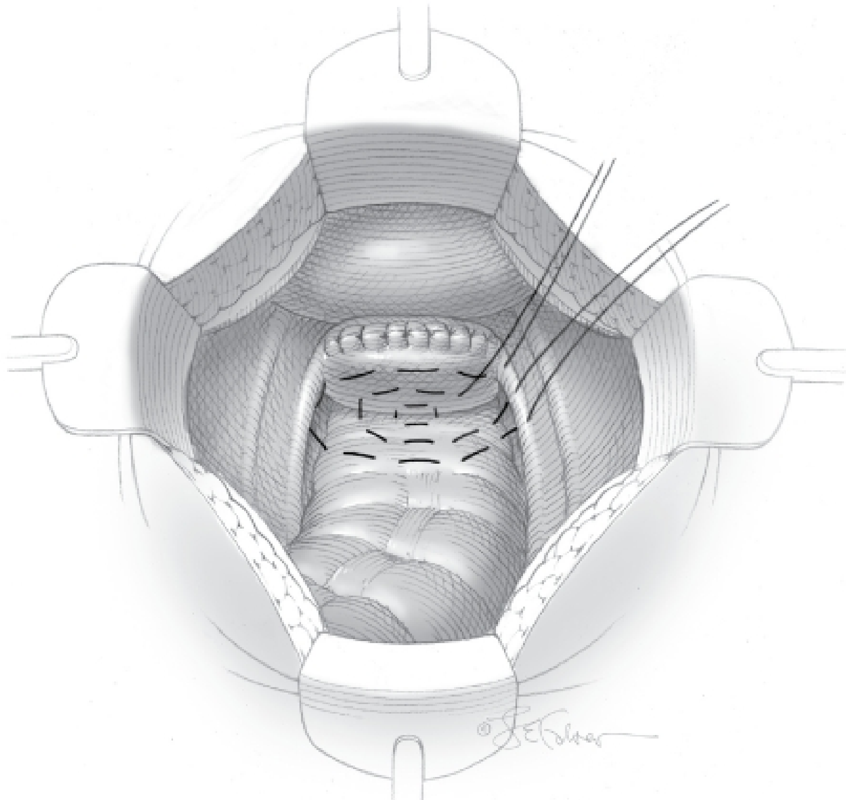
3. **Special Considerations.** Following completion of initial procedures, the cul-de-sac is exposed and evaluated for suture placement. Additionally, end-to-end anastomosis (EEA) sizers may be placed within the vagina or rectum to identify borders and allow correct suture placement. Prior to culdoplasty, both ureters should be re-identified.

   In the past, these procedures have focused on suturing peritoneal and serosal surfaces. However, a more effective approach incorporates deep bites into the muscularis of the vagina and sigmoid, taking care to avoid both bowel and vaginal lumens. During placement of rectosigmoid sutures, attempts should be made to avoid adjacent rectosigmoid veins because hematomas form commonly. If bleeding develops, direct vascular compression provides effective control in most instances.

4. **Halban Culdoplasty.** Several rows of sutures are placed longitudinally through the serosa and muscularis of the sigmoid (Fig. 42-22.1). Attention is given to avoiding entry into the lumen. The same sutures then are advanced through the

peritoneum of the deep cul-de-sac and up toward the apex of the posterior vaginal wall. As much of the cul-de-sac as possible should be obliterated, but to avoid ureteral injury, sutures never should be placed lateral to the uterosacral ligaments.

FIGURE 42-22.1

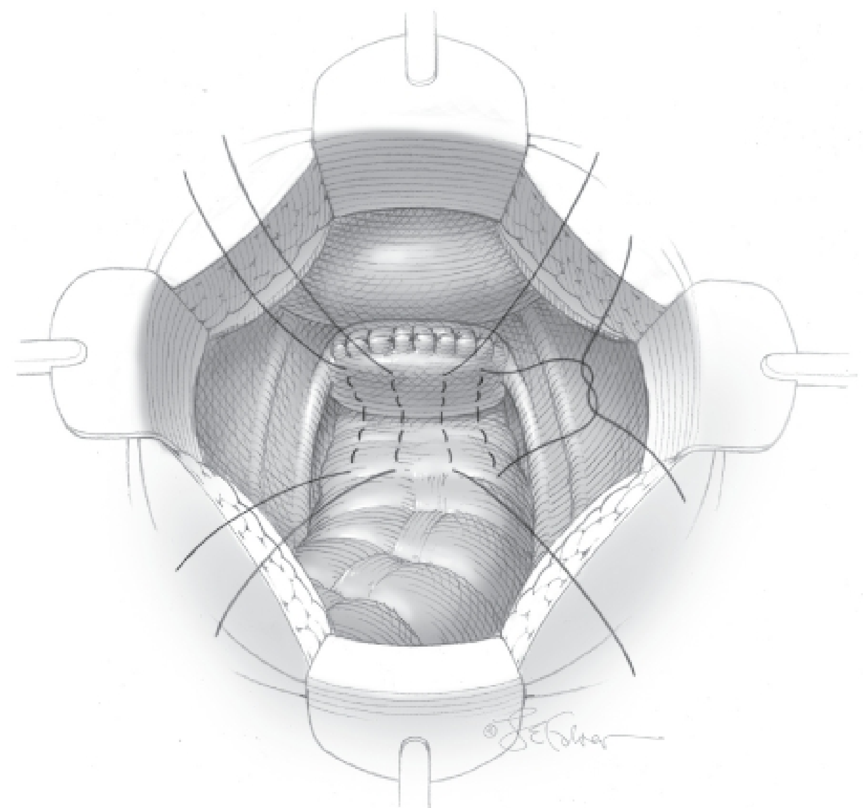


Source: Schorge JO, Schaffer JI, Halvorson LM, Hoffman BL, Bradshaw KD, Cunningham FG: *Williams Gynecology*: http://www.accessmedicine.com

Halban culdoplasty.

5. **Moschcowitz Culdoplasty.** Concentric sutures are placed in the cul-de-sac beginning at the base and are directed upward almost to the level of the vaginal apex (Fig. 42-22.2). During placement, sutures are placed through the posterior vaginal wall and then advanced through the right uterosacral ligament, the sigmoid colon muscularis, and finally, the left uterosacral ligament. The number of concentric rings required depends on the depth of the cul-de-sac, and usually three to four rings is sufficient. With this procedure, ureteral kinking should be avoided during suture tying.

FIGURE 42-22.2



Source: Schorge JO, Schaffer JI, Halvorson LM, Hoffman BL, Bradshaw KD, Cunningham FG: *Williams Gynecology*: http://www.accessmedicine.com

Moschcowitz culdoplasty.

6. **Cystoscopy.** Consideration should be given to performing cystoscopy after sutures are tied because of the potential risk of ureteral injury with culdoplasty procedures.

7. **Incision Closure.** The abdominal incision is closed as described in Section 41-1, Midline Vertical Incision or 41-2, Pfannenstiel Incision.

Postoperative

Following culdoplasty, postoperative care follows that for any major abdominal surgery. Hospitalization typically varies from 2 to 4 days, and return of normal bowel function usually dictates this course. Stool softeners should be administered because defecatory dysfunction can develop because of a change in the rectosigmoid angle. These may be continued as needed to maintain normal bowel function.

42-23 LEFORT PARTIAL COLPOCLEISIS

There are two basic approaches to the repair of vaginal vault prolapse: obliterative and reconstructive. Although reconstructive approaches recreate a functional vagina, obliterative procedures reach nearly 100 percent success rates in curing prolapse.

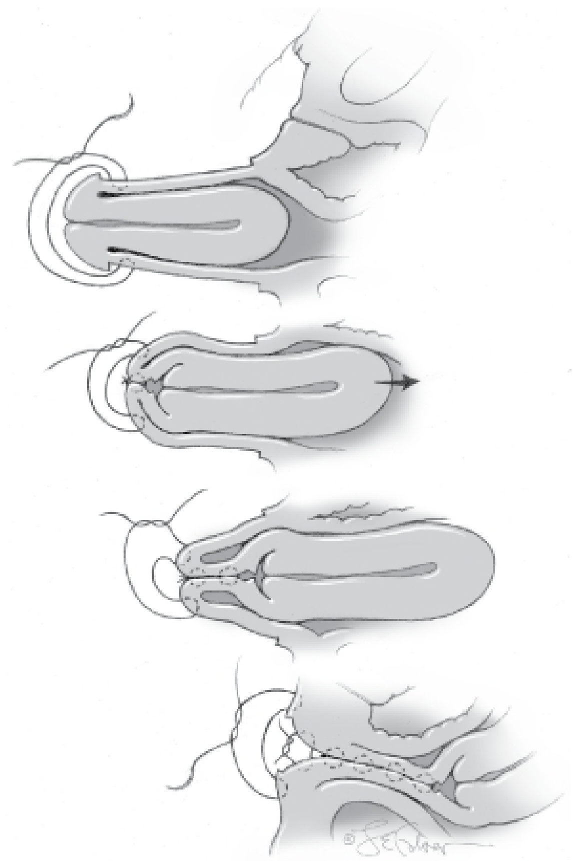
The Lefort partial colpocleisis is an obliterative vaginal procedure that approximates the anterior and posterior vaginal walls. This surgery effectively replaces the prolapsed vagina vault into the abdominal cavity in women with or without a uterus (Fig. 42-23.1).

The procedure is performed in women with significant prolapse of the uterus, vagina, and anterior and posterior vaginal walls beyond the hymen.

As opposed to complete colpocleisis, with Lefort partial colpocleisis, the vaginal muscosa is not excised in its entirely. Rather, rectangular sections of vaginal mucosa are dissected from the anterior and posterior vaginal walls, and the denuded fibromuscular layers are sewn together to close the vaginal vault. The remaining lateral tracts of vaginal epithelium create drainage tunnels on either side of the closed vagina.

This operation may be performed quickly with general, regional, or local anesthesia. Blood loss is minimal, and success rates are high. The procedure is indicated only in elderly women who have no future desire for sexual intercourse. Because of the high incidence of stress urinary incontinence (SUI) following Lefort partial colpocleisis, concurrent anti-incontinence surgery should be considered. Additionally, high perineorrhaphy is recommended to decrease the risk of recurrent prolapse.

FIGURE 42-23.1



Source: Schorge JO, Schaffer JI, Halvorson LM, Hoffman BL, Bradshaw KD, Cunningham FG: *Williams Gynecology*: http://www.accessmedicine.com

Prolapse correction following placement of serial sutures.

Preoperative

PATIENT EVALUATION

Because access to the cervix and endometrial cavity is not possible following this procedure, preinvasive lesions should be excluded. Accordingly, a normal Pap smear should be documented prior to surgery, and evaluation of the endometrium with either endometrial biopsy or sonography is recommended.

Prolapse of the anterior, posterior, and apical compartments should be documented prior to surgery (see Chap. 24, Visual Descriptors). Additionally, urodynamic testing is performed prior to surgery to evaluate for potential SUI (see Chap. 23, Diagnostic Testing). Even without documented SUI, an adjunctive anti-incontinence procedure should be considered to prevent postoperative incontinence. Additionally, in patients undergoing Lefort partial colpocleisis who have large, global prolapse, intravenous pyelography or cystoscopy is warranted to assess for ureteral obstruction preoperatively.

CONSENT

Women considering this procedure must be fully aware that future vaginal intercourse will not be possible. Therefore, the decision to undergo this procedure should include a woman's partner. Patients expressing hesitation or doubt should be excluded as candidates.

Risks of the procedure include urinary incontinence, urinary retention, ureteral obstruction, and recurrent prolapse. Additionally, in the unlikely situation that malignancy of the cervix or endometrium develops after Lefort partial colpocleisis, the diagnosis potentially may be delayed.

PATIENT PREPARATION

Bowel preparation is administered the evening prior to surgery to effectively empty and decompress the rectum (see Table 39-10). This minimizes fecal contamination of the surgical field. Antibiotic prophylaxis is administered routinely to lower rates of postoperative wound infection.

Intraoperative

Surgical Steps

1. **Anesthesia and Patient Positioning.** General or regional anesthesia is preferred, although Lefort partial colpocleisis can be performed under local anesthesia. A patient is placed in high lithotomy position, the vagina is surgically prepared, and a Foley catheter is placed. Although Lefort partial colpocleisis may be performed in women with or without a uterus, the following description outlines the steps in women without previous hysterectomy.

2. **Vaginal Marking.** The rectangular areas of vaginal mucosa on the anterior and posterior vaginal walls are outlined with a surgical marker or electrosurgical blade. The size of the rectangular sections to be removed is determined by the length of vaginal wall. The distal transverse incision should be placed 1 to 2 cm above the cervical os. The proximal transverse incision should lie 2 to 3 cm below the urethral meatus. The width of the incision will be determined by the size of the uterus, cervix, and vaginal walls and should be almost as wide as the prolapsed bulge. This allows multiple sutures to be placed during closure.

3. **Vaginal Infiltration.** The rectangular areas of the vaginal wall to be removed are thoroughly infiltrated with 50 mL of a dilute hemostatic solution (20 units of vasopressin in 60 mL of saline). This infiltration should extend beyond the anticipated incision boundaries. Without infiltration, significant bleeding can result from disruption of multiple small vessels during dissection.

4. **Vaginal Incision.** Previously outlined areas are incised sharply down to the fibromuscular layer.

5. **Vaginal Dissection.** A combination of sharp and blunt dissection is used to lift the mucosa away from the fibromuscular layer (Figs. 42-23.2 and 42-23.3). Dissection in the correct plane will prevent inadvertent entry into the bladder or bowel. The technique for dissection involves a finger behind the vaginal wall and dissection with Metzenbaum scissors parallel to the vaginal wall. After entry into the correct plane, blunt dissection with a sponge may allow rapid and wide development of this avascular space.

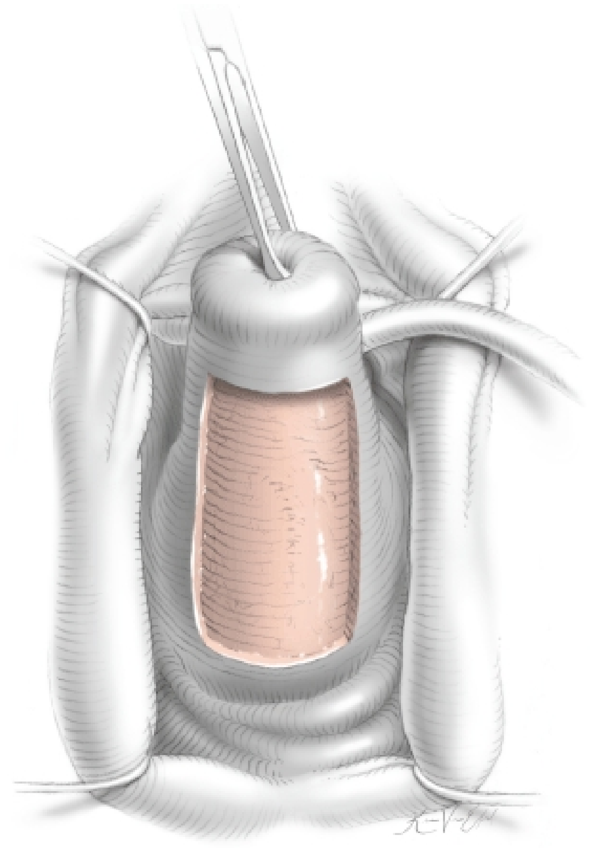
Anterior vaginal wall incision.

FIGURE 42-23.3



Source: Schorge JO, Schaffer JI, Halvorson LM, Hoffman BL, Bradshaw KD, Cunningham FG: *Williams Gynecology*: http://www.accessmedicine.com

Posterior vaginal wall incision.

6. **Suture Placement.** After rectangles are removed, a row of interrupted stitches using 2-0 permanent suture is placed from the anterior to the posterior distal transverse edges (Fig. 42-23.4). These will effectively close the fibromuscular layer over the cervix.

   In creating lateral vaginal drainage canals along both the right and left sides of the incision, sutures approximate the superior and inferior edges of the rectangles. Each lateral row of sutures begins distally and progresses proximally to the original proximal transverse incision (Fig. 42-23.5).

   To elevate and replace the uterus into the pelvic cavity, the surgeon places progressively more caudad rows of interrupted sutures that approximate the anterior and posterior fibromuscular layers along the width of the incision (Fig. 42-23.6). Successive transverse tiers of sutures are placed until the proximal transverse incision is reached (Fig. 42-23.7). These rows create a tissue septum that elevates and supports the uterus (Fig. 42-23.1).

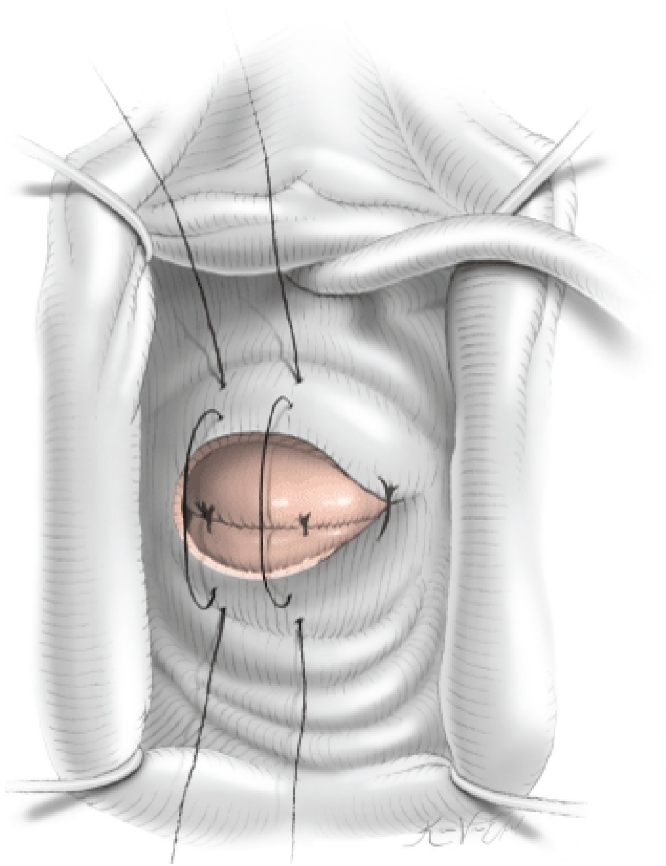
Subsequent rows of sutures.

7. **Anti-incontinence Surgery.** At this point, an anti-incontinence procedure may be performed.

8. **Closure of the Vaginal Mucosa.** The vaginal mucosa then is closed in a running fashion with 2-0 delayed-absorbable suture, taking wide bites through the vaginal epithelium (Fig. 42-23.8).

FIGURE 42-23.8



Source: Schorge JO, Schaffer JI, Halvorson LM, Hoffman BL, Bradshaw KD, Cunningham FG: *Williams Gynecology*: http://www.accessmedicine.com

Vaginal mucosa closure.

9. **Perineorrhaphy.** Following closure of the vaginal mucosa, perineorrhaphy is performed as describe in Section 42-16, Perineorrhaphy.

10. **Cystoscopy.** Cystoscopy should be performed at the end of the procedure to exclude urinary tract injury and document ureteral patency (see Section 42-1, Diagnostic and Operative Cystoscopy and Urethroscopy).

Postoperative

Postoperative bladder function will depend on whether anti-incontinence surgery is performed. In general, recovery with Lefort partial colpocleisis is quick and typically without complication. Postoperative drainage should not be anticipated save for mild spotting. As with any prolapse procedure, constipation should be avoided, and administration of stool softeners is recommended. Resumption of normal activities is encouraged, with the exception of heavy lifting for several months.

42-24 COMPLETE COLPOCLEISIS

Complete colpocleisis, also termed *colpectomy,* is an obliterative procedure used for those with posthysterectomy global prolapse who do not desire future sexual activity. If the uterus is present, concurrent total vaginal hysterectomy and closure of the peritoneum are performed prior to colpocleisis.

As opposed to Lefort partial colpocleisis, with complete colpocleisis, the vaginal wall is excised in its entirety. During complete colpocleisis, the epithelial and lamina proprial layers are removed down to the fibromuscular layer (see Fig. 38-17). The operation attaches the anterior fibromuscular layer to the posterior fibromuscular layer, effectively closing the vaginal tube and replacing it back into the abdominal cavity.

The operation effectively obliterates the vagina, removing any potential for sexual intercourse. Thus the operation generally is performed in elderly women. It also may be considered in those with high surgical risks because it can be performed quickly under local or regional anesthesia and with minimal blood loss. Complete colpocleisis should be performed in conjunction with high perineorrhaphy to decrease the risk of recurrence. Consideration also should be given to performing a prophylactic anti-incontinence procedure, even in those without incontinence symptoms, because the risk of postoperative stress urinary incontinence is high.

Preoperative

PATIENT EVALUATION

This procedure is used in patients who have complete eversion of the apical, anterior, and posterior vaginal walls (see Fig. 24-8C). Women with this severe degree of prolapse often do not have stress urinary incontinence (SUI) because the urethra is kinked by prolapsing organs. However, with replacement of the prolapse, many patients do develop postoperative SUI. Therefore, urodynamic testing traditionally has been performed prior to this procedure (see Chap. 23, Diagnostic Testing). Anti-incontinence surgery is recommended for those who demonstrate latent SUI.

Frequently, women with global prolapse have some degree of ureteral obstruction. Accordingly, consideration should be given to obtaining a preoperative intravenous pyelogram (IVP) or performing cystoscopy to document ureteral patency. If ureteral patency is not confirmed, then preoperative stent placement should be considered (see Section 42-1, Diagnostic and Operative Cystoscopy and Urethroscopy).

CONSENT

Women must have absolutely no intention or desire for future intercourse. Partners should be included in the decision and consent process. Women who express any hesitancy or doubt should be excluded as candidates. Stress urinary incontinence is a definite risk with this surgery. If patients decline anti-incontinence operations, they should be aware of the significant risk of postoperative urinary incontinence.

As with any prolapse surgery, the consent process should include a discussion of the risk of prolapse recurrence, although this risk is low with complete colpocleisis. Additionally, ureteral injury also has been described with this procedure, and it should be included on consenting documents.

PATIENT PREPARATION

Bowel preparation is administered the evening prior to surgery to effectively empty and decompress the rectum (see Table 39-10). This minimizes fecal contamination of the surgical field. Antibiotic prophylaxis is administered routinely to lower rates of postoperative wound infection (see Table 39-7).

Intraoperative

Surgical Steps

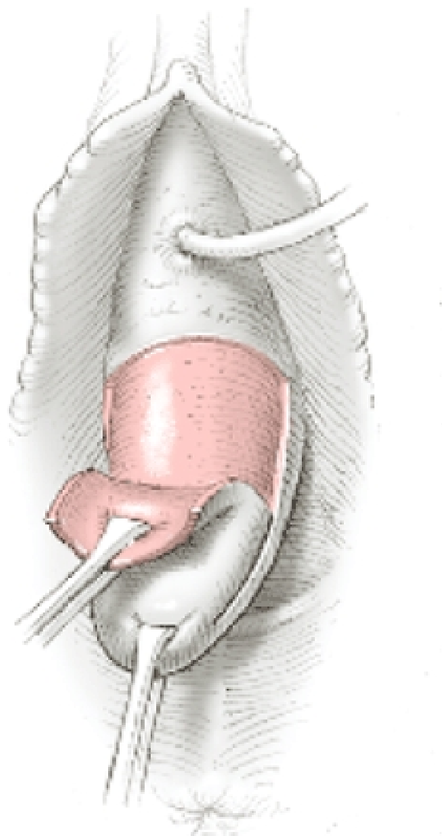
1. **Anesthesia and Patient Positioning.** General or regional anesthesia is preferred, although complete colpocleisis can be performed with local anesthesia. Following anesthesia administration, the woman is placed in high lithotomy position, the vagina is surgically prepared, and a Foley catheter is placed.

2. **Vaginal Infiltration.** Allis clamps are place laterally at 3 and 9 o'clock inside the hymenal ring and pulled to the midline without tension. This maneuver allows the surgeon to assess the amount of vaginal wall to be removed. The vaginal wall then is infiltrated thoroughly with 50 mL of a dilute hemostatic solution (20 units of vasopressin in 60 mL of saline). Without infiltration, significant blood loss can occur from disruption of multiple small vessels during dissection.

3. **Vaginal Incision.** A circumferential incision is made inside the hymenal ring around the base of the prolapsed vaginal tube. The incision should begin approximately 3 cm below the urethral meatus to allow concurrent anti-incontinence procedures.

4. **Vaginal Dissection.** A combination of sharp and blunt dissection is used to lift the vaginal epithelium and lamina propria off the fibromuscular layer (Figs. 42-24.1 and 42-24.2). Dissection in this correct plane will prevent inadvertent entry into the bladder or bowel. The technique for dissection involves positioning a finger behind the vaginal wall and dissecting with Metzenbaum scissors parallel to the vaginal wall. After entry into the correct plane, blunt dissection with a sponge may allow rapid and wide development of this avascular space. There are areas where dissection may be difficult. For example, in reaching the vaginal apex and the remnants of the uterosacral ligaments, extensive scarring may be present and requires sharp dissection. The entire vaginal epithelium is removed from the prolapsed vaginal tube.

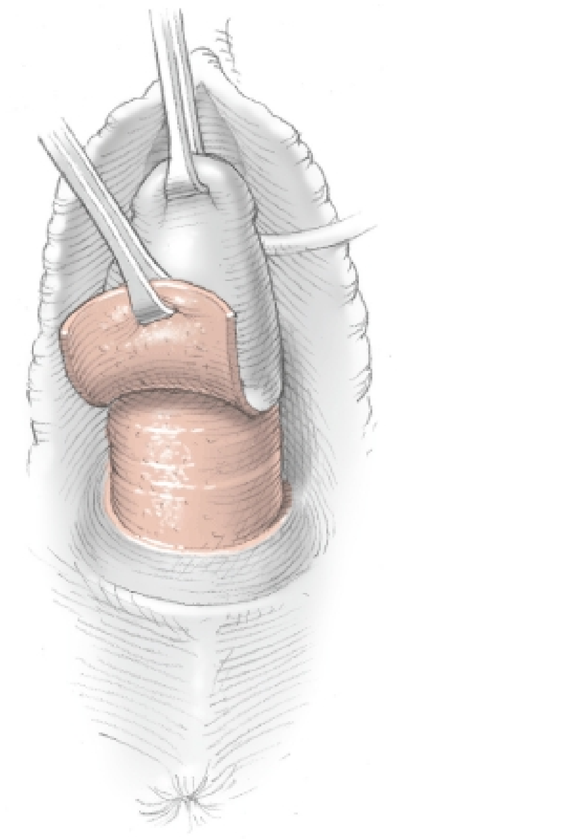
FIGURE 42-24.1



Source: Schorge JO, Schaffer JI, Halvorson LM, Hoffman BL, Bradshaw KD, Cunningham FG: *Williams Gynecology*: http://www.accessmedicine.com

Anterior vaginal wall incision.

FIGURE 42-24.2



Posterior vaginal wall incision.

5. **Suture Placement.** To plicate the anterior and posterior vaginal walls together and replace the vaginal tube into the abdominal cavity, the surgeon places a series of circumferential purse-string sutures around the vaginal tube within the fibromuscular layer using 2-0 permanent suture (Fig. 42-24.3).

   The first bite is taken at 12 o'clock at the distal end of the prolapsed tube. Bites are taken circumferentially around the vaginal tube, and the knot is secured at 12 o'clock. A hemostat is placed 1 cm above the knot, and the suture ends are cut. The next circumferential suture then is place 1 cm proximal to the first suture. Prior to securing the knot on this second suture, the surgeon presses the hemostat into the apex of the vaginal tube, telescoping the tube cephalad, toward the abdominal cavity (Fig. 42-24.4A). The knot then is secured over the hemostat, effectively reducing this section of prolapsed vaginal tube. The hemostat then is removed and placed on the second suture, and the process is repeated. Depending on the size of the prolapse, approximately six to eight sutures are needed to completely invert the prolapsed vaginal tube (Fig. 42-24.4B).

FIGURE 42-24.3

A. Cephalad pressure against telescoping vaginal tube as serial sutures are secured. **B.** Completely inverted vaginal tube.

6. **Anti-incontinence Surgery.** At this point, an anti-incontinence procedure may be performed.

7. **Closure of Vaginal Mucosa.** The vaginal mucosa then is closed with a running technique using 2-0 delayed-absorbable suture, taking wide bites through the vaginal epithelium. The completed incision lies approximately 2 to 3 cm above the hymenal ring.

8. **Perineorrhaphy.** At this point, perineorrhaphy is performed, as describe in Section 42-16, Perineorrhaphy.

9. **Cystoscopy.** Cystoscopy should be performed at the procedure's completion and ureteral patency documented.

Postoperative

Postoperative bladder function will depend on whether anti-incontinence surgery is performed. In general, recovery with colpocleisis is quick and typically without complication. Postoperative drainage should not be anticipated save for mild spotting. As with any prolapse procedure, constipation should be avoided, and administration of stool softeners is recommended. Resumption of normal activities is encouraged, with the exception of heavy lifting for several months.

42-25 ANAL SPHINCTEROPLASTY

Anal sphincteroplasty re-approximates disrupted skeletal muscle fibers of the external anal sphincter (EAS) and disrupted smooth muscle fibers of the internal anal sphincter (IAS). Re-approximation may be accomplished by directly joining the ends of disrupted fibers, termed an *end-to-end sphincteroplasty.* Alternatively, disrupted ends may be overlapped and then sutured, called an *overlapping sphincteroplasty.*

Both techniques can be used to repair a third- or fourth-degree laceration immediately following a delivery or may be used in a nonobstetric setting to treat anal incontinence. Although incontinence secondary to sphincter disruption stands as a clear indication, surgical correction also may benefit those with incontinence from other etiologies, including pudendal neuropathy.

Preoperative

PATIENT EVALUATION

Some causes of anal incontinence are more amenable to surgical correction than others. For this reason, careful preoperative

evaluation should attempt to distinguish underlying sources. Evaluation for structural gastrointestinal (GI) tract pathology typically involves colonoscopy and/or barium enema. Additionally, radiographic bowel transit studies can be used to diagnose slow transit time, which may be related to symptoms of defecatory dysfunction.

Specific to the anorectum, endoanal sonography can accurately define structural disruption of the EAS and IAS (see Chap. 25, Pudendal Nerve Terminal Motor Latency Test). Anal manometry and pudendal nerve conduction studies may identify physiologic dysfunction such as neuropathy (Martinez Hernandez, 2003).

Clinicians have attempted to improve success rates by selecting only those women who may benefit most from surgery. Investigations have evaluated patient age, preoperative anal manometry readings, and pudendal nerve motor function as possible predictors of outcome. However, research findings have been conflicting, and none of these predictors has proven to be a consistent indicator of success (Bravo Gutierrez, 2004; Buie, 2001; Gearhart, 2005; Gilliland, 1998).

CONSENT

Although a significant number of women may have improved incontinence immediately following anal sphincteroplasty, the durability of this repair is poor. For example, 3 to 5 years following repair, only about 10 percent of women are fully continent to solid and liquid stool (Halverson, 2002; Malouf, 2000). The causes of long-term deterioration in function remain uncertain, but the effects of aging, postoperative scarring, and progressing pudendal neuropathy have been suggested (Madoff, 2004). In addition, it is believed that skeletal muscle repair has poor success because resting muscle tone places incision lines on constant tension. Therefore, preoperative counseling should inform that although most individuals will improve after the procedure, continence is rarely perfect, and deterioration of continence typically progresses with time.

In addition to persistent incontinence, sphincteroplasty is associated with other surgical risks. More common serious complications include wound dehiscence and fistula formation. For example, Ha and co-workers (2001) noted wound complications in 12 percent and fistula formation in 4 percent.

PATIENT PREPARATION

Because of the high associated risk of wound complications, antibiotic prophylaxis is warrant to minimize wound infection following surgical contamination from vaginal and rectal flora. We use a combination of ciprofloxican and metronidazole to obtain broad bacterial coverage. Additionally, bowel preparation is administered the night before surgery.

Intraoperative

Surgical Steps

1. **Anesthesia and Patient Positioning.** After administration of either general or regional anesthesia, the patient is placed in dorsal lithotomy position, the vagina and perineum are surgically prepared, and a Foley catheter is inserted into the bladder.

2. **Incision and Dissection.** A downward arching curvilinear incision is placed between the fourchette and anus. This incision connects with a midline vaginal incision (Fig. 42-25.1). The incised edges are placed on tension with Allis clamps. Metzenbaum scissors are used to dissect disrupted ends of the EAS from surrounding and intervening scar tissue. Because of extensive scarring found frequently around these muscles, fibers may be difficult to isolate, and a nerve stimulator or a needle tip electrosurgical blade can assist in delineating these fibers. Scar tissue in the midline may be cut but should not be excised because this tissue is used in the sphincteroplasty repair to add strength to the muscle closure.

   The internal anal sphincter contributes significantly to the resting tone of the anal canal, and closure of this muscle should be included in the repair. The IAS is identified as a smooth white sheet of tissue deep to the external sphincter and superficial to the rectal wall (Fig. 42-25.2).

FIGURE 42-25.1

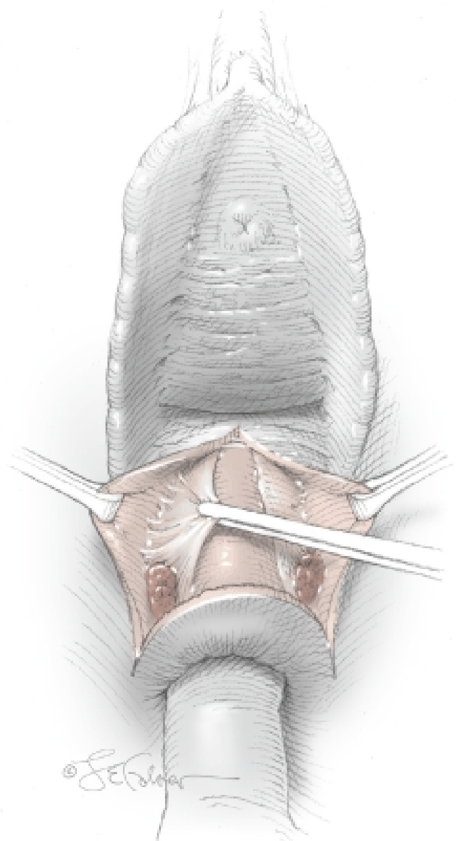
Vaginal dissection.

FIGURE 42-25.2

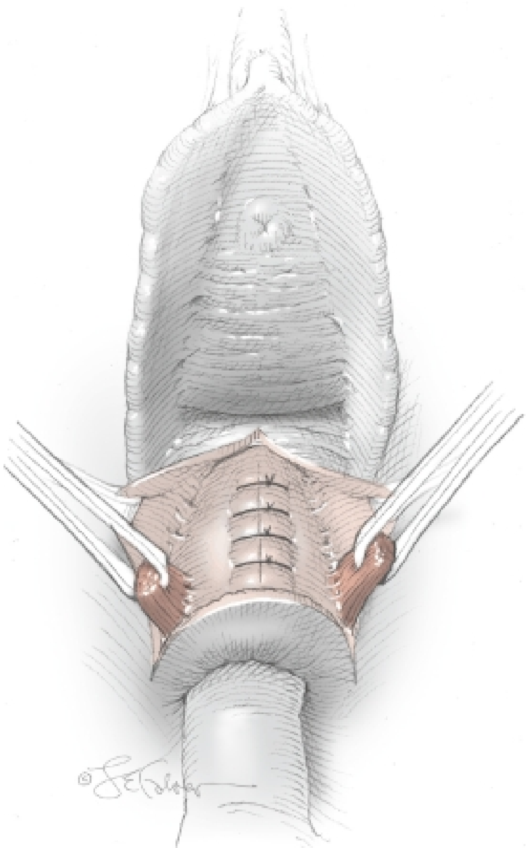


Source: Schorge JO, Schaffer JI, Halvorson LM, Hoffman BL, Bradshaw KD, Cunningham FG: *Williams Gynecology*: http://www.accessmedicine.com

Internal anal sphincter identification.

3. **Suture Placement within the Internal Anal Sphincter.** Interrupted stitches of 3-0 delayed-absorbable suture are used to bring the edges of the anal sphincter together in the midline (Fig. 42-25.3). Sutures are spaced approximately 0.5 cm apart, and a second row of sutures may be placed after the first is completed. Suture placement and exposure of the IAS are aided by a finger in the rectum.

FIGURE 42-25.3



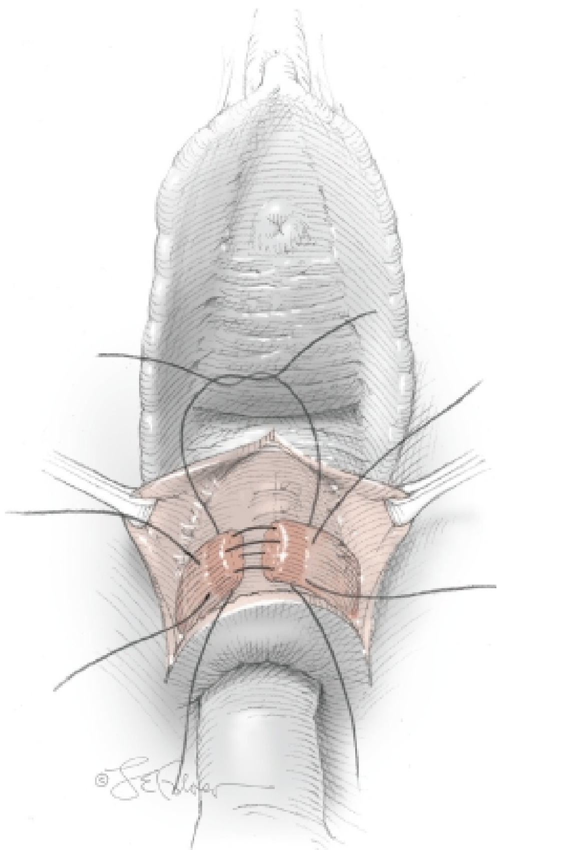
Source: Schorge JO, Schaffer JI, Halvorson LM, Hoffman BL, Bradshaw KD, Cunningham FG: *Williams Gynecology*: http://www.accessmedicine.com

External anal sphincter is identified and grasped.

4. **Levator Ani Muscle Plication.** For additional support, the levator ani muscle can be plicated with interrupted stitches using 2-0 delayed-absorbable suture. This is performed after IAS closure but prior to EAS closure.

5. **Suture Placement for End-to-End External Anal Sphincteroplasty.** Each end of the disrupted EAS is identified and grasped with an Allis clamp. The ends of the EAS are brought to the midline, and a row of interrupted re-approximating stitches is placed (Fig. 42-25.4). Although many surgeons prefer the durability of permanent sutures for most pelvic reconstructive procedures, use of permanent sutures for sphincteroplasty has been associated with high rates of suture erosion and wound dehiscence (Luck, 2005). For this reason, 2-0 delayed-absorbable suture is used.

FIGURE 42-25.4

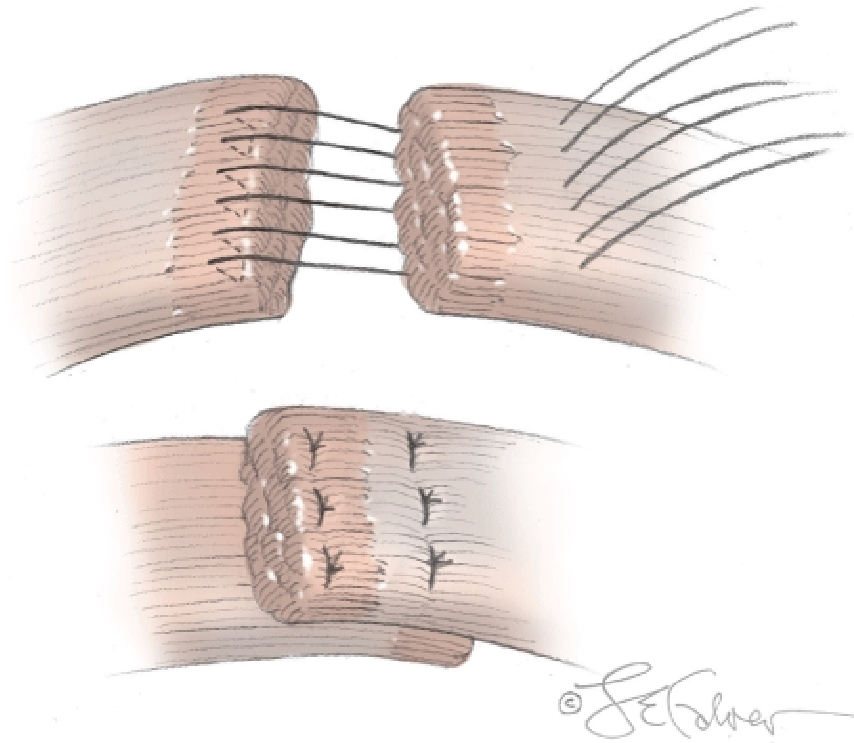


Source: Schorge JO, Schaffer JI, Halvorson LM, Hoffman BL, Bradshaw KD, Cunningham FG: *Williams Gynecology*: http://www.accessmedicine.com

End-to-end sphincteroplasty.

6. **Suture Placement for Overlapping External Anal Sphincteroplasty.** With overlapping sphincteroplasty, at least 1 cm of the EAS is mobilized on each side. The ends are grasped with Allis clamps and brought to the midline, where they are overlapped. The overlapped ends are then sewn together with interrupted stitches of 2-0 delayed-absorbable suture placed in two rows, each containing two to three stitches (Fig. 42-25.5).

FIGURE 42-25.5



Source: Schorge JO, Schaffer JI, Halvorson LM, Hoffman BL, Bradshaw KD, Cunningham FG: *Williams Gynecology*: http://www.accessmedicine.com

Overlapping sphincteroplasty.

7. **Incision Closure.** Excision of excess perineal skin may be required prior to closing the incision. Vaginal and perineal skin then is closed in a running fashion using 2-0 delayed-absorbable suture.

Postoperative

Pain varies postoperatively, and some women can be discharged home on day 1, whereas others require longer hospitalization. The Foley catheter is removed on postoperative day 1 or 2. An active voiding trial is performed, and some women may have difficulty voiding because of pain, inflammation, and levator ani muscle spasm. To limit trauma to the healing repair, we attempt to delay defecation for several days. Patients do not eat or drink on day 1 and are subsequently advanced to clear liquids for 3 or 4 days. Stool softeners are given when a solid diet is begun and continued for at least 6 weeks. Because of the high risk of wound dehiscence and infection, oral ciprofloxacin and metronidazole are given for 10 days after the procedure. Local wound care involves sitz baths twice daily and perineal cleansing with a plastic water bottle following urination or defecation. Ambulation is encouraged, but physical exercise and sexual intercourse are delayed for 8 weeks. The first postoperative visit typically is 4 weeks following surgery.

42-26 RECTOVAGINAL FISTULA REPAIR

In general, rectovaginal fistulas that are encountered by gynecologists include those complicating fourth-degree obstetric lacerations. Less commonly, fistulas may result from gynecologic surgery or radiation therapy.

If a fistula is identified at the time or shortly after injury, then immediate repair may be undertaken. However, fistulas should not

be repaired in the setting of inflammation, induration, or infection. In addition, fistulas that are associated with radiation therapy and recurrent fistulas often require interposition of a vascular flap, such as a Martius bulbocavernosus fad pad graft, because of poor tissue vascularity (see Section 42-11, Martius Bulbocavernosus Fat Pad Flap).

Approaches to fistula repair include perineoproctotomy or transvaginal, transperineal, or transrectal techniques. The favored approach by gynecologists is the transvaginal approach and is described below. Perineoproctotomy is not recommended unless fistulas include the anal sphincter. This technique involves disruption of the anal sphincter to access the fistula and as a result, increases the risk of anal incontinence postoperatively.

Preoperative

PATIENT EVALUATION

A thorough evaluation is necessary to delineate the full extent of a fistula. If there are questions about the complexity or number of fistulas, then imaging as discussed in Chapter 26, Classification may be needed. At times, pinpoint fistulas are difficult to identify and may require examination under anesthesia with lacrimal duct probing.

CONSENT

In addition to general surgical risks, specific risks following rectovaginal fistula repair include fistula recurrence, dyspareunia, and vaginal narrowing or shortening. Fecal incontinence may follow some cases if the anal sphincter is disrupted during surgery, as with perineoproctotomy.

PATIENT PREPARATION

A rigorous bowel preparation is required to clear all stool from the rectal vault. For this reason, clear-liquid diet and an orally administered polyethylene glycol and electrolyte solution (Go-lytely, Braintree Laboratories, Braintree, MA) are advised the day prior to surgery. If stool is still present in the rectum at the beginning of surgery, then a povidone-iodine flush (Betadine, Purdue Pharma, Stamford, CT) with a Mallencot drain may be needed. Antibiotic prophylaxis is given concurrent with surgery, however, additional doses during the days before surgery are not indicated.

Intraoperative

Surgical Steps

1. **Anesthesia and Patient Position.** Rectovaginal fistula repair typically is an inpatient procedure performed under general or regional anesthesia. The patient is placed in high lithotomy position with stirrups of the surgeon's choosing. The vagina is surgically prepared, and a Foley catheter is placed.

2. **Fistula Identification.** The fistula is identified, and its course is traced with the use of a probe or dilator. Moreover, small fistulas may be dilated to improve identification of the tract.

3. **Vaginal Incision.** A circular incision is made in the vaginal epithelium surrounding the fistula (Fig 42-26.1). The incision must be wide enough to allow excision of the tract and permit sufficient mobilization of surrounding tissues to close the defect without excess tissue tension (Fig. 42-26.2). The vaginal epithelium around the tract is excised sharply. The entire fistula tract then is excised (Fig. 42-26.3).

FIGURE 42-26.1

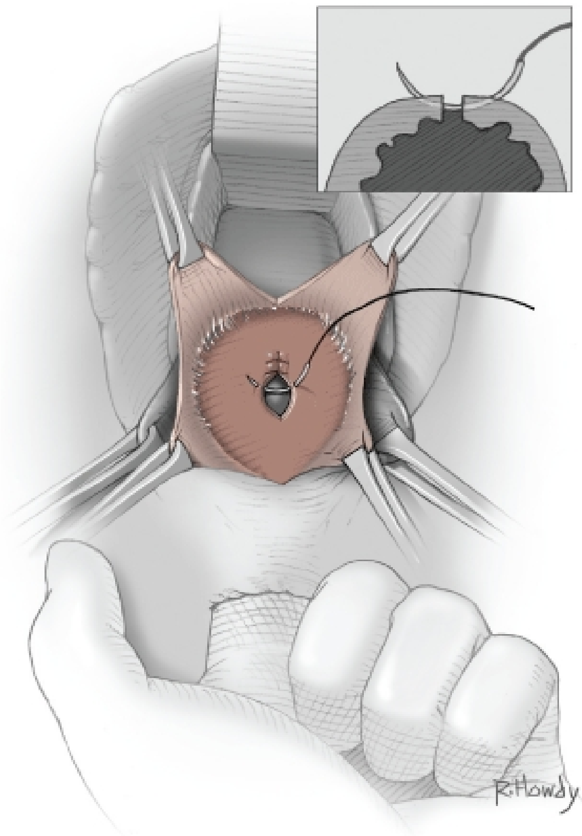
Fistulous tract excision.

4. **Closure of the Rectal Wall.** Using 3-0 delayed-absorbable suture, a purse-string suture is placed around the defect a few millimeters from the mucosal edge. This suture is tied and inverts the defect's edges into the bowel lumen. One or two additional purse-string sutures may be placed in the rectal wall muscularis to re-inforce the closure. Alternatively, the defect may be closed with serial interrupted sutures placed within the rectal wall muscularis (Fig. 42-26.4).

FIGURE 42-26.4

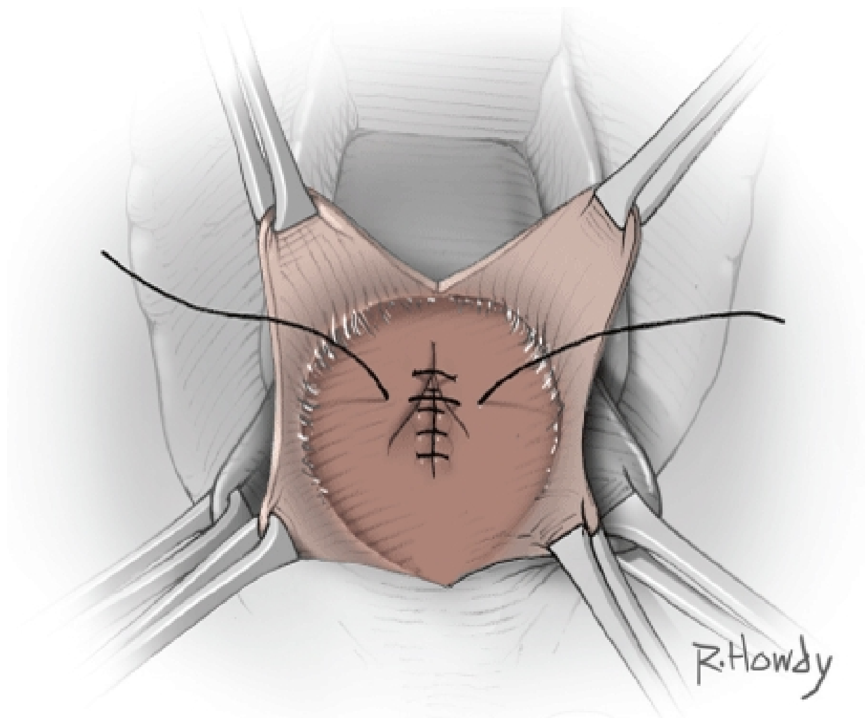


Source: Schorge JO, Schaffer JI, Halvorson LM, Hoffman BL, Bradshaw KD, Cunningham FG: *Williams Gynecology*: http://www.accessmedicine.com

Closure of the rectal wall.

5. **Closure of the Fibromuscular Layer.** The fibromuscular layer between the vagina and rectum is then re-approximated with interrupted stitches of 2-0 delayed-absorbable sutures (Fig. 42-26.5). If possible, two layers of closure are completed to minimize incision tension and re-inforce the repair.

FIGURE 42-26.5



Source: Schorge JO, Schaffer JI, Halvorson LM, Hoffman BL, Bradshaw KD, Cunningham FG: *Williams Gynecology*: http://www.accessmedicine.com

Closure of the fibromuscular layer.

6. **Martius Bulbocavernosus Fat Pad Graft.** In cases in which avascular or fibrotic tissue is extensive, a Martius graft may be placed between the fibromuscular layer and vaginal epithelium (see Section 42-11, Martius Bulbocavernosus Fat Pad Flap).

7. **Vaginal Wall Closure.** Excess vaginal mucosa is trimmed, and the vaginal mucosa is closed with a continuous running method using 3-0 absorbable or delayed-absorbable suture.

Postoperative

Normal activity can resume during the first postoperative days. Intercourse, however, should be delayed at least 1 month or until the vaginal incision is healed.

To limit trauma to the healing repair, we try to delay defecation for several days. Patients do not eat or drink on the first postoperative day and are advanced subsequently to clear liquids for 3 or 4 days. Stool softeners are given when a solid diet is begun and continued for at least 6 weeks. Constipation should be avoided. Local wound care involves sitz baths twice daily and perineal cleansing with a plastic water bottle following urination or defecation.

43-1 RADICAL ABDOMINAL HYSTERECTOMY (TYPE III)

Radical hysterectomy differs from simple hysterectomy in that additional surrounding soft tissue is resected to achieve negative tumor margins. The operation involves wide radical excision of the parametrial and paravaginal tissues in addition to removal of pelvic lymphatics.

The five types of extended hysterectomy are discussed in Chapter 30, Radical Hysterectomy. Of these, type III (radical) hysterectomy is indicated for stage IB1 to IIA cervical cancer, for clinical stage II endometrial cancer when tumor has extended to the cervix, and for small central recurrences of cervical cancer following radiation therapy (Coleman, 1994; Cornelison, 1999).

Type III radical hysterectomy is performed most commonly abdominally. Laparoscopically assisted radical vaginal hysterectomy, however, is currently being investigated as a less invasive alternative (Hertel, 2003).

Radical hysterectomy is a dynamic operation that requires significant intraoperative decision making. Every step requires a focused, consistent surgical approach. In many ways, radical hysterectomy defines the field of gynecologic oncology, and its principles are applicable to a variety of other surgical procedures performed commonly.

Preoperative

PATIENT EVALUATION

Pelvic examination under anesthesia with cystoscopy and proctoscopy is not mandatory for all women, but clinical staging procedures should be completed. For some women with larger cervical tumors, an abdominal-pelvic computed tomographic (CT) scan may be indicated. To a lesser degree, positron-emission tomography (PET) scanning also has application in identifying metastatic disease before proceeding with radical hysterectomy (see Chap. 2, Positron Emission Tomography Imaging) (Chou, 2006).

CONSENT

Radical hysterectomy can result in significant morbidity and potentially unforeseen short- and long-term complications. These complications develop more frequently in women with obesity, prior pelvic infections, and prior abdominal surgery, which may add difficulty to performing radical hysterectomy safely (Cohn, 2000). In addition, differences in patient morbidity rates among surgeons do exist and may be of significant magnitude (Covens, 1993).

Of potential intraoperative complications, the most common is acute hemorrhage. Blood loss averages 500 to 1,000 mL, and transfusion rates are variable but high (Lentz, 1998; Rutledge, 2004). Preoperative autologous blood donation and intraoperative red cell salvage are both feasible, but their use differs significantly among surgeons (see Chap. 40, Preoperative Autologous Donation). Overall, neither strategy is consistently used (Covens, 1997; Mirhashemi, 1999).

Subacute postoperative complications may include ureterovaginal or vesicovaginal fistula (1 to 2 percent), lymphocyst formation (5 percent), and significant postoperative bladder or bowel dysfunction (20 percent) (Averette, 1993; Fotiou, 1994; Jackson, 2006). Additionally, long-term effects on sexual function, loss of fertility, and other body functions should be reviewed candidly (Bergmark, 1999).

The tone of the consenting process should reflect the extent of the operation required to hopefully cure or at least begin treatment of the malignancy. Importantly, a patient must be advised that the procedure may be aborted if metastatic disease or pelvic tumor extension is found (Leath, 2004).

PATIENT PREPARATION

A blood sample should be typed and crossed for potential transfusion. Pneumatic compression devices or subcutaneous heparin or both are particularly important because of the long anticipated length of surgery and long postoperative recovery (see Chap. 39, Prophylaxis Options) (Martino, 2006).

Bowel preparation with a polyethylene glycol electrolyte solution (GoLYTELY, Braintree Laboratories, Braintree, MA) is not mandatory but may be indicated in some circumstances. Inadvertent bowel injury should be rare unless extenuating circumstances are identified, such as previous bowel surgery, known adhesions, or prior pelvic infections.

Perioperative antibiotic prophylaxis with a third-generation cephalosporin such as cefoxitin is sufficient to prevent most surgical site-related infections. High-volume blood loss rapidly clears antibiotics from the operative site during radical hysterectomy compared with extrafascial hysterectomy. For this reason, one dose is given preoperatively and a second perioperatively (Bouma, 1993; Sevin, 1991).

CONCURRENT SURGERY

Early-stage cervical cancer is most likely to spread via the lymphatics, thus requiring adjunctive node removal (see Fig. 30-4). Pelvic lymphadenectomy typically is completed just before or immediately after radical hysterectomy. Para-aortic lymphadenectomy also may be indicated in some circumstances (see Sections 43-9, Pelvic Lymphadenectomy and 43-10, Para-Aortic Lymphadenectomy) (Angioli, 1999).

Since spread to the adnexa is much less common than via the lymphatics, removal should depend on a woman's age and potential for metastases (Shimada, 2006). In candidates for ovarian preservation, transposition of ovaries out of the pelvis may be considered in young women when postoperative radiation is anticipated (see Chap. 28, Ovary and Pregnancy Outcomes). However, in transposed ovaries, symptomatic periadnexal cysts are commonplace, and sustained ovarian function may not result (Buekers, 2001).

Intraoperative

Surgical Steps

1. **Anesthesia and Patient Positioning.** General anesthesia is mandatory, but epidural placement may aid effective postoperative pain control and decrease duration of postoperative ileus (Leon-Casasola, 1996). Bimanual examination always should be performed in the operating room before scrubbing to re-orient the surgeon to patient anatomy. Supine positioning is appropriate in most cases.

2. **Abdominal Entry.** A midline vertical abdominal incision is most common. It provides excellent exposure but typically prolongs hospital stays and increases postoperative pain (see Section 41-1, Midline Vertical Incision). Alternatively, a Cherney or Maylard incision offers postoperative advantages found with transverse incisions and allows access to the lateral pelvis (see Sections 41-3, Cherney Incision and 41-4, Maylard Incision). However, upper para-aortic nodes may not be accessible through these incisions. Pfannenstiel incisions offer limited exposure and should be reserved only for selected patients (see Section 41-2, Pfannenstiel Incision) (Orr, 1995).

3. **Exploration.** Following abdominal entry, a surgeon first should explore the abdomen thoroughly for obvious metastatic disease. Suspicious lymph nodes and any other lesions should be removed or biopsied. Confirmation of metastatic disease or pelvic tumor extension should prompt the surgeon to decide whether to proceed or abort an operation based on overall intraoperative findings and the clinical situation (Leath, 2004).

4. **Entering the Retroperitoneal Space.** The uterus is placed on traction with curved Kelly clamps at the cornua. The round ligament is sutured with 0-gauge delayed-absorbable suture as laterally as possible, and the tie is held on tension to aid entry into the retroperitoneal space. The round ligament is transected, and the broad ligament beneath separates into thin anterior and posterior leaves that contain loose areolar connective tissue between.

   The anterior leaf of the broad ligament is placed on traction and is dissected sharply to the vesicouterine fold. The posterior leaf of the broad ligament then is placed on traction and dissected sharply along the pelvic sidewall parallel to the

infundibulopelvic (IP) ligament.

5. **Ureter Isolation.** Loose areolar connective tissue of the lateral retroperitoneal space is dissected bluntly until the external iliac artery is palpated just medial to the psoas major muscle. The index and middle fingers then are placed on either side of the artery, and the areolar connective tissue is dissected bluntly by a "walking" motion toward the patient's head (Fig. 43-1.1).

   The medial peritoneal leaf of the broad ligament is elevated and placed on traction to permit direct identification of the common iliac artery bifurcation and origins of the external and internal iliac arteries. Blunt dissection with a finger or suction tip is used in a sweeping motion from top to bottom along the medial peritoneal leaf to identify and sufficiently mobilize the ureter, which crosses at this bifurcation.

   A Babcock clamp is used to grasp the ureter, and a Mixter right-angle clamp is used to "pop" through an underlying avascular space. A 1/4 -in-wide Penrose drain then is pulled through this space to isolate the ureter and assist in identifying its location throughout the remainder of surgery.

FIGURE 43-1.1

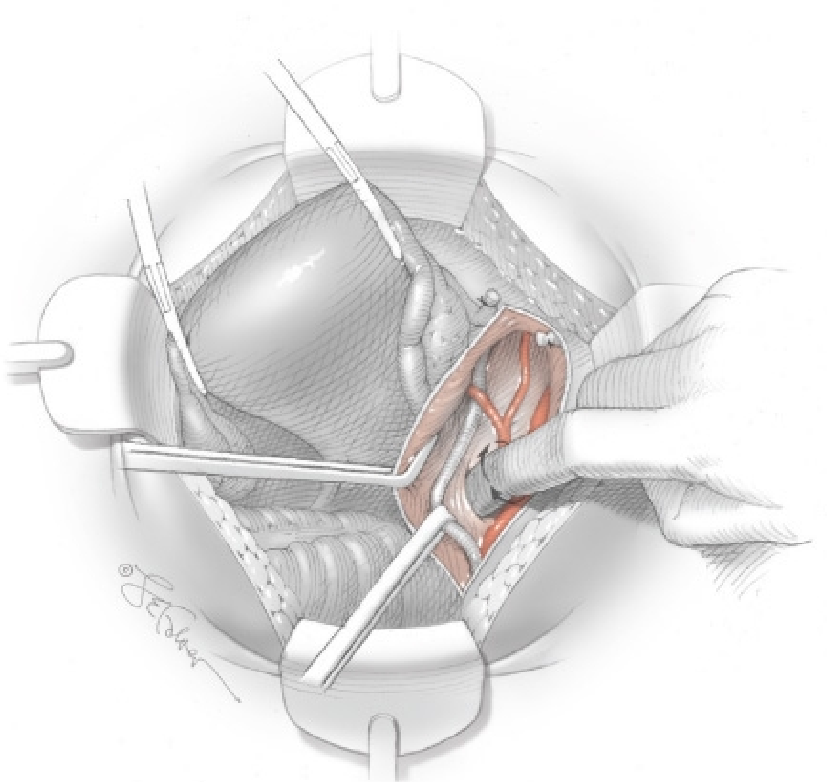
Finding the ureter.

6. **Creating Spaces.** The pararectal space is developed by gently placing the right index finger between the internal iliac artery and the ureter and tracking in a gentle swirling motion at a 45-degree angle downward toward the midline aiming for the coccyx (Fig. 43-1.2).

Subsequently, the paravesical space is formed by holding the lateral tie of the round ligament and bluntly following the external iliac artery to the pelvic bone. The index, middle, and ring fingers of the right hand then are swept horizontally toward the midline.

FIGURE 43-1.2



Source: Schorge JO, Schaffer JI, Halvorson LM, Hoffman BL, Bradshaw KD, Cunningham FG: *Williams Gynecology*: http://www.accessmedicine.com

Making the pararectal space.

7. **Uterine Artery Ligation.** Reflection of the lateral peritoneal fold of the anterior broad ligament just distal to the round ligament should reveal the superior vesical artery (see Fig. 38-15). This vessel is dissected bluntly to better define its location and then grasped with a Babcock clamp and placed on traction. A right-angle clamp is "popped" through and beneath to create a space large enough to accommodate a narrow curved Deaver retractor. This maneuver places the superior vesical artery on traction, prevents its inadvertent ligation, and aids location of the uterine artery (Fig. 43-1.3).

   The surgeon's left hand is inserted into the pelvis with the middle finger placed in the paravesical space, the index finger in the pararectal space, and the uterus with attached Kelly clamps cupped in the palm. The uterus is held on firm traction to expose the lateral pelvic sidewall. To visualize the uterine artery, the surgeon sharply dissects parametrial attachments and intervening areolar connective tissue beginning at the internal iliac artery and continuing caudally to the superior vesical artery. The origin of the uterine artery lies between these two vessels.

   Tissues immediately proximal and distal to the uterine artery are dissected bluntly, and a right-angle clamp is placed beneath this artery to retrieve a 2-0 silk suture. The uterine artery tie is placed as close as possible to its origin from the internal iliac artery. The process is repeated to place a separate silk suture far enough medial to enable vessel transection (Fig. 43-1.3).

Silk ties help to identify the proximal and distal portions of the uterine artery throughout the remainder of the operation. A small vascular clip (Hemoclip, Weck, Research Triangle Park, NC) also can be placed lateral to the silk tie on the proximal uterine artery for additional security of hemostasis. The uterine artery then is cut. The underlying uterine vein also then may be isolated, clipped or tied, and cut.

FIGURE 43-1.3

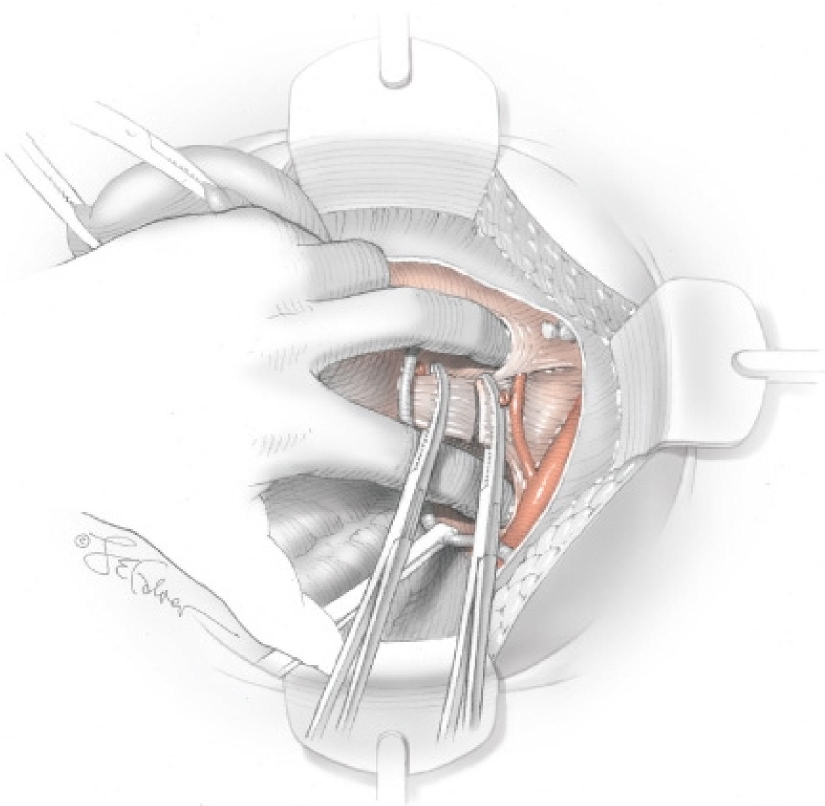
Ligating the uterine artery.

8. **Uniting Paravesical and Pararectal Spaces.** The parametrial tissues have been pressed together by development of the paravesical and pararectal spaces. Parametrial resection to unite the spaces can be performed by several methods: (1) clamping, cutting, and suturing (Fig. 43-1.4), (2) stapling with gastrointestinal anastomosis stapler, and (3) electrosurgical blade dissection to the pelvic sidewall using a right-angle clamp to elevate and isolate parametrial tissue. Dissection is continued until the parametrium overlying the ureter is mobile.

FIGURE 43-1.4

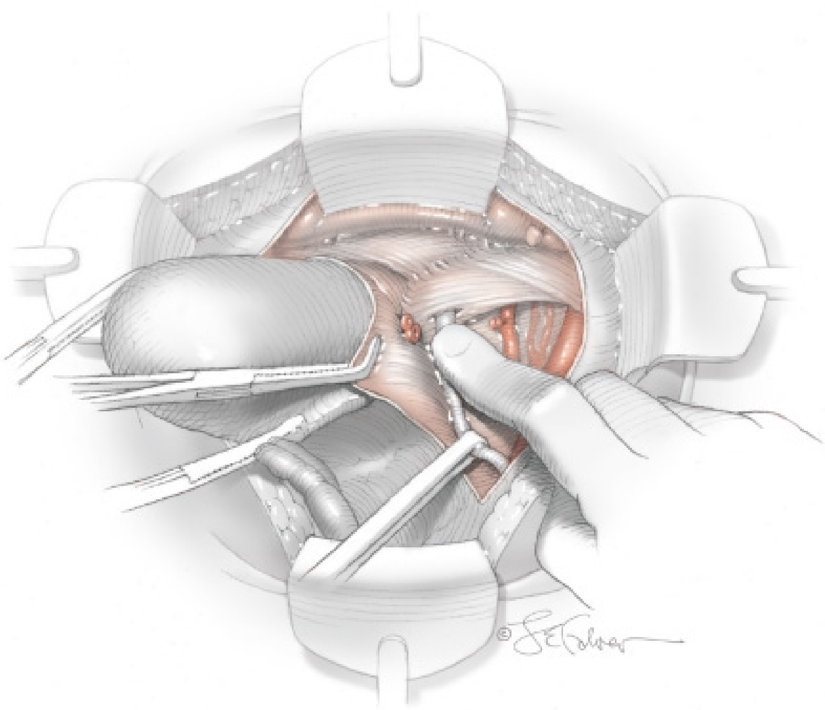


Source: Schorge JO, Schaffer JI, Halvorson LM, Hoffman BL, Bradshaw KD, Cunningham FG: *Williams Gynecology*: http://www.accessmedicine.com

Uniting the spaces.

9. **Ureter Mobilization.** Tips of a right-angle clamp are positioned perpendicular to and just above the ureter to detach it from the medial leaf of the peritoneum. Opening the tips parallel to the ureter creates a plane that permits it to be dissected bluntly away from the peritoneum. The ureter is placed on gentle traction by grasping the previously placed Penrose drain with the left hand. The right index finger carefully sweeps the ureter downward and laterally until a tunnel through the paracervical tissue can be palpated ventromedially as the ureter enters this tissue (Fig. 43-1.5). Additional parametrial dissection often is required to ensure that the uterine artery and surrounding soft tissue have been lifted medially over the ureter.

FIGURE 43-1.5



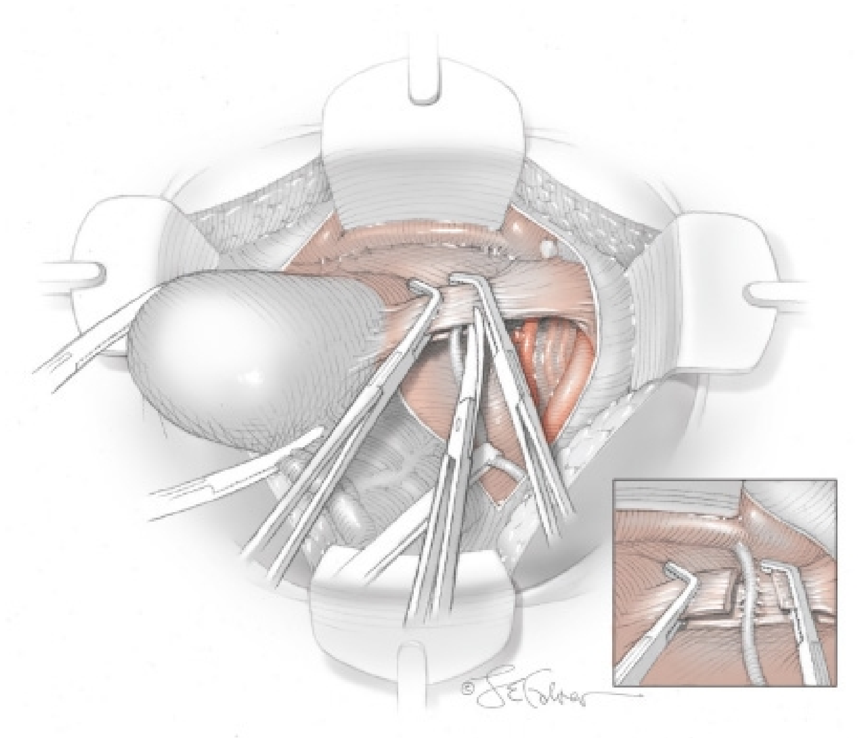
Source: Schorge JO, Schaffer JI, Halvorson LM, Hoffman BL, Bradshaw KD, Cunningham FG: *Williams Gynecology*: http://www.accessmedicine.com

Mobilizing the ureter.

10. **Bladder Dissection.** Electrosurgical dissection is performed to free the bladder distally from the cervix and onto the upper vagina. This may need to be repeated several times as the tunnel is progressively unroofed and the ureter is more directly visible. The bladder eventually will need to be dissected several centimeters distal to the cervical portio and onto the upper vagina.

11. **Unroofing the Ureteral Tunnel.** The uterus is placed on lateral traction, and the proximal ureter is held on traction by gently pulling on the Penrose drain. The tunnel opening should be palpated and a right-angle clamp inserted with tips directed upward while direct visualization of the underlying ureter is confirmed. The tips are directed medially toward the cervix and "popped" through the paracervical tissue. A second clamp is placed through the opening. The ureter can be dissected bluntly and pushed posteriorly toward the tunnel floor. It should be visible below before cutting the overlying paracervical tissue (Fig. 43-1.6). Delayed-absorbable 3-0 suture ties are placed for hemostasis. The same procedure may be repeated several times to completely unroof the tunnel and entirely expose the ureter. The dissection should proceed in a proximal to distal fashion with direct visualization of the ureter at all times to prevent its injury. After unroofing the ureter, it is retracted upward, and filmy attachments between the ureter and tunnel bed are sharply divided.

FIGURE 43-1.6



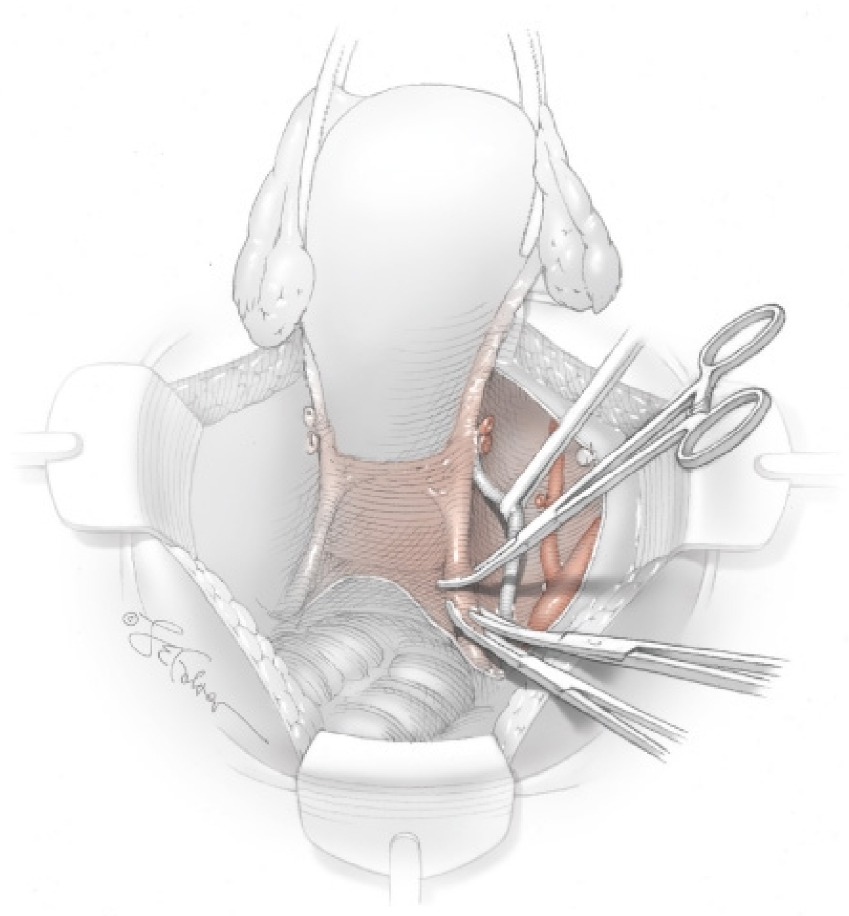
Source: Schorge JO, Schaffer JI, Halvorson LM, Hoffman BL, Bradshaw KD, Cunningham FG: *Williams Gynecology*: http://www.accessmedicine.com

Unroofing the ureteral tunnel.

12. **Uterosacral Resection.** Posterior radical dissection often is best performed near the operation's end because exposed retroperitoneal tissues typically ooze until the vaginal cuff is closed. The cervical external os is palpated, and an electrosurgical blade is used to superficially incise or "score" the peritoneum between the uterosacral ligaments.

    A plane is developed by gently pressing a finger toward the vaginal wall without poking through into the vault. This rectovaginal plane should be developed by gentle pressure toward the sacrum and enlarged laterally until three fingers can be inserted comfortably. This maneuver frees the rectosigmoid away from the uterosacral ligaments and prevents inadvertent bowel injury. Remaining peritoneal attachments are dissected sharply to fully expose the rectovaginal space. The exposed uterosacral ligaments can be visualized, palpated, clamped at the pelvic sidewall. They are cut and ligated with 0-gauge delayed-absorbable suture (Fig. 43-1.7). This procedure may need to be repeated to complete transection of the uterosacral ligament and adjacent supportive tissues.

FIGURE 43-1.7

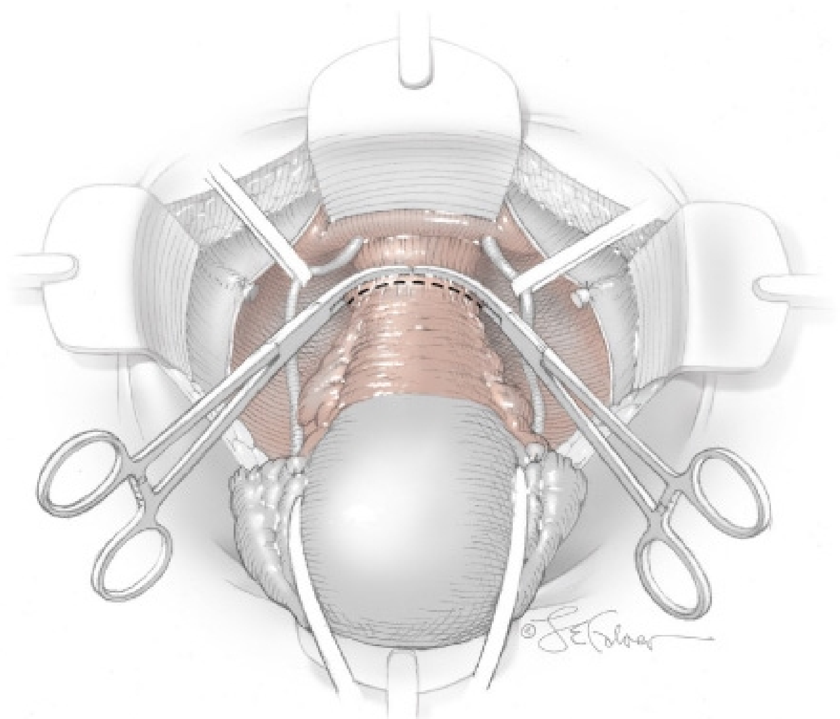


Source: Schorge JO, Schaffer JI, Halvorson LM, Hoffman BL, Bradshaw KD, Cunningham FG: *Williams Gynecology*: http://www.accessmedicine.com

Uterosacral resection.

13. **Vaginal Resection.** At this surgical point, a radical hysterectomy specimen should be held in place only by the paracolpium and vagina. The bladder and ureters are further bluntly and sharply dissected free until at least 3 cm of upper vagina will be included with the resected specimen. Curved clamps are placed on the lateral paracolpium with the ureter directly visible laterally. The paracolpium is cut and suture ligated with 0-gauge delayed-absorbable suture. The upper vagina then can either be: (1) clamped, cut, and suture ligated, (2) stapled, or (3) sharply transected with an electrosurgical blade and suture ligated (Fig. 43-1.8). The specimen should be examined carefully to ensure an adequate upper vaginal segment and grossly negative surgical margins.

FIGURE 43-1.8



Source: Schorge JO, Schaffer JI, Halvorson LM, Hoffman BL, Bradshaw KD, Cunningham FG: *Williams Gynecology*: http://www.accessmedicine.com

Vaginal resection.

14. **Suprapubic Catheter Placement** . Placement of a suprapubic catheter may aid postoperative voiding trials in carefully selected, motivated patients (Nwabineli, 1993). Through a stab incision in the lateral abdominal wall, the tip of a second Foley catheter is directed into the abdomen. The Foley catheter already within the bladder is held firmly and anteriorly in a distal extraperitoneal location. A 5-mm transverse incision is made through the mucosa of the bladder's dome using an electrosurgical blade set to a cutting mode. The Foley bulb should be directly visible, and the bladder mucosal edges are held with two Allis clamps. The second Foley catheter tip is inserted into the bladder and the balloon inflated. A snug but not tight purse-string chromic suture is placed around the bladder defect and tied. Delayed-absorbable suture in a running fashion is used to "bury" the visible Foley catheter tubing in a tunnel to its exit at the pelvic sidewall. The Foley catheter should be fixed at the skin with a permanent suture that does not occlude the tubing. The urethral Foley catheter can be discontinued postoperatively when urine is seen to be draining from the suprapubic catheter.

    Alternatively, a sole urethral Foley catheter may be placed and drainage continued until postvoid residual volumes measure below 100 mL.

15. **Ovarian Transposition.** Optionally, for those in whom preservation of ovarian function is desired, adnexa may be transposed. A distal portion of the adnexa is grasped with a Babcock clamp and placed on traction. Dissection is performed to free the IP ligament so that the adnexa can be lifted into the upper abdomen. A large vascular clip is placed on the ovary at the residual utero-ovarian ligament stump. This allows postoperative visualization of ovarian location by radiography or CT scan. Additionally, a 0-gauge silk suture is placed at this stump site and tied. Its needle is left in place.

    A hand-held abdominal retractor then is used to expose an area of the lateral posterior peritoneum as high as possible in the abdomen. The silk suture needle then is placed through the peritoneum, the adnexum is elevated by this "pulley stitch", and the suture is tied.

Dissection of the IP from the pelvic sidewall to mobilize the ovary for transposition creates a sidewall defect. The lateral pelvic defect is closed with a continuous stitch using 0-gauge delayed-absorbable suture to prevent internal herniation. The ovaries should be inspected before abdominal closure to exclude vascular compromise by transposition.

16. **Final Steps.** Active bleeding should be controlled immediately when the radical hysterectomy specimen has been removed. A dry laparotomy sponge then may be held firmly deep in the pelvis for several minutes to tamponade raw surfaces. With bleeding controlled, a surgeon should assess the vascular support to the ureter and other sidewall structures. To structures that appear particularly devascularized, an omental J-flap may provide additional blood supply (see Section 43-3, Total Pelvic Exenteration) (Fujiwara, 2003; Patsner, 1997). Routine pelvic suction drainage and closure of the peritoneum are not necessary (Franchi, 1997; Srisomboon, 2002).

Postoperative

Immediate postoperative care following radical hysterectomy in general follows that for laparotomy. Early ambulation after radical hysterectomy is especially important to prevent thromboembolic complications (Stentella, 1997). Early feeding, including rapid initiation of a clear-liquid diet, also may shorten the hospital stay (Kraus, 2000). Tenesmus, constipation, and incontinence are common immediate symptoms that should improve significantly months or years later (Butler-Manuel, 1999; Sood, 2002).

Bladder tone returns slowly, and a major cause is thought to be partial sympathetic and parasympathetic denervation during radical dissection (Chen, 2002). Thus, Foley catheter drainage commonly is continued until a patient is passing flatus because improving bowel function typically accompanies resolving bladder hypotonia. Removal of the catheter or clamping of the suprapubic tube should be followed by a successful voiding trial (see Chap. 39, Voiding Trials). A voiding trial may be attempted prior to hospital discharge or at the first postoperative visit. Patients with adequate voiding should be instructed to press gently on the suprapubic area for several days afterwards to help empty the bladder completely and prevent retention. Successful voiding may take several weeks to achieve.

Nerve-sparing radical hysterectomy is a new method demonstrating an improvement in postoperative bladder function (Raspagliesi, 2006). However, many patients have pre-existing abnormal urodynamic findings that are simply exacerbated by radical hysterectomy (Lin, 1998, 2004). In the 3 percent of women who develop long-term bladder hypotonia or atony, intermittent self-catheterization is preferred to indwelling urinary catherization (Chamberlain, 1991; Naik, 2005).

Although cervical cancer survivors treated with radical hysterectomy have much better sexual functioning than those who receive radiation therapy, more than half of surgical patients report a worse sex life postoperatively (Butler-Manuel, 1999). Severe orgasmic problems and uncomfortable intercourse due to a reduced vaginal size may develop but often resolve within 6 to 12 months. However, lack of sexual interest and lubrication may persist long-term or permanently (Jensen, 2004). Disturbances of vaginal blood flow response during sexual arousal may account for much of the reported constellation of symptoms (see Chap. 13, Arousal) (Maas, 2004). Eventually, women treated by surgery alone can expect a quality of life and overall sexual function similar to those of peers without a history of cancer (Frumovitz, 2005).

43-2 MODIFIED RADICAL ABDOMINAL HYSTERECTOMY (TYPE II)

Four procedural differences distinguish a modified radical hysterectomy (type II) from the more radical type III procedure. First, the uterine artery is transected where it crosses the ureter (instead of at its origin from the internal iliac artery). Second, only the medial half of the cardinal ligament is resected (instead of division at the sidewall). Additionally, the uterosacral ligament is divided halfway between the uterus and sacrum (instead of at the sacrum). And lastly, a smaller 2- to 3-cm margin of upper vagina is removed (instead of 3 to 4 cm). These modifications serve to reduce surgical time and associated morbidity while still enabling complete resection of smaller cervical tumors (Landoni, 2001).

Clear indications for modified radical hysterectomy are few and controversial (Rose, 2001). Stage IA2 cervical cancer is the most common presenting diagnosis (Orlandi, 1995). Type II hysterectomy is also performed on occasion for: (1) preinvasive or microinvasive disease when a more invasive lesion cannot be excluded, (2) selected stage IB1 disease with less than 2-cm lesions, and (3) small central postirradiation recurrences (Coleman, 1994; Magrina, 1999; Photopulos, 1991). In addition, a variation of

this operation may be performed when more extensive dissection is required for known benign disease (Fedele, 2005). Anatomic landmarks that distinguish a type II hysterectomy are somewhat vague and thereby allow a surgeon to sculpt the procedure to the patient's specific situation (Fedele, 2005).

Modified radical hysterectomy is performed most commonly abdominally. However, laparoscopically assisted modified radical vaginal hysterectomy is being investigated currently as a less invasive alternative (Eisenkop, 2005; Querleu, 2002).

Preoperative

Preparation for surgery should proceed with the same care and discretion that are essential for the success of radical (type III) hysterectomy (see Section 43-1, Radical Abdominal Hysterectomy (Type III)).

Intraoperative

Surgical Steps

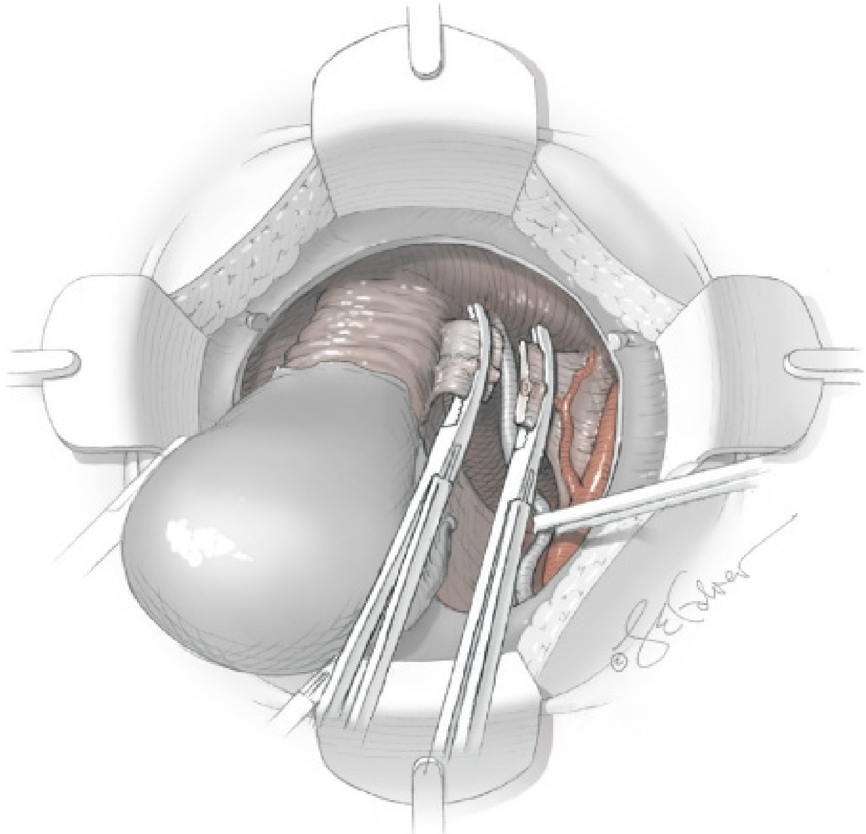
1. **Anesthesia and Patient Positioning.** Modified radical hysterectomy is performed under general anesthesia with the patient supine. Bimanual examination always should be performed in the operating room before scrubbing to re-orient the surgeon to patient anatomy. The abdomen is surgically prepared, and a Foley catheter is placed.

2. **Abdominal Entry.** Modified radical hysterectomy may be performed safely through a midline vertical or transverse incision (see Sections 41-1, Midline Vertical Incision through 41-4, Maylard Incision) (Fagotti, 2004).

3. **Retroperitoneal Dissection.** The initial steps of a modified radical (type II) hysterectomy mirror those of the type III procedure. The retroperitoneum is opened to identify structures, the ureter is mobilized, and the paravesical and pararectal spaces are developed to exclude the possibility of parametrial tumor extension before proceeding with this less radical operation (see Section 43-1, Radical Abdominal Hysterectomy (Type III)) (Scambia, 2001).

4. **Uterine Artery Ligation.** At this point, type II hysterectomy begins to differ from the radical type III procedure. The superior vesical artery does not have to be identified, nor does the entire extent of the internal iliac artery need to be dissected free of adventitial tissue. The ureteral tunnel opening should be palpated and the uterine vessels divided at that location (Fig. 43-2.1). Ligation of the uterine artery as it crosses the ureter allows preservation of distal ureteral blood supply.

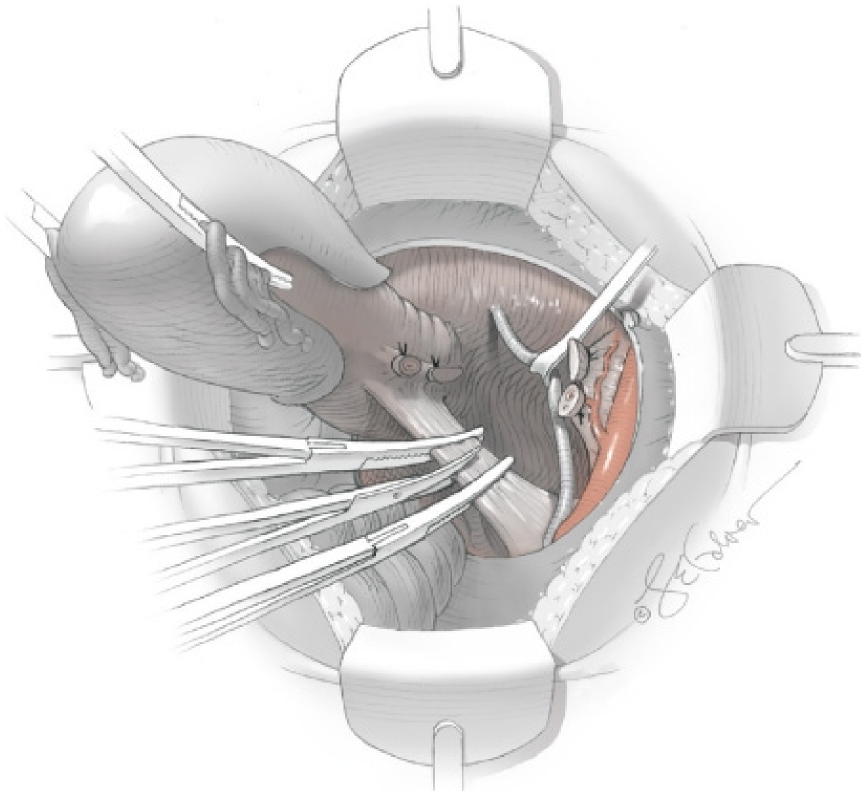
FIGURE 43-2.1



Uterine artery ligation.

5. **Cardinal Ligament Resection.** The bladder is mobilized distally off the cervix and onto the upper vagina (see Section 43-1, Radical Abdominal Hysterectomy (Type III)). Parametrial tissue at the sidewall does not have to be mobilized over the ureter in a type II hysterectomy. Posterior attachments of the ureter remain intact, and only the medial half of the cardinal ligaments are resected by successive clamping, cutting, and suture ligation of the paracervical tissue medial to the ureter. In contrast to the type III hysterectomy, the ureter is not dissected out of the tunnel bed but is rolled laterally to expose the medial cardinal ligament (Fig. 43-2.2).

FIGURE 43-2.2

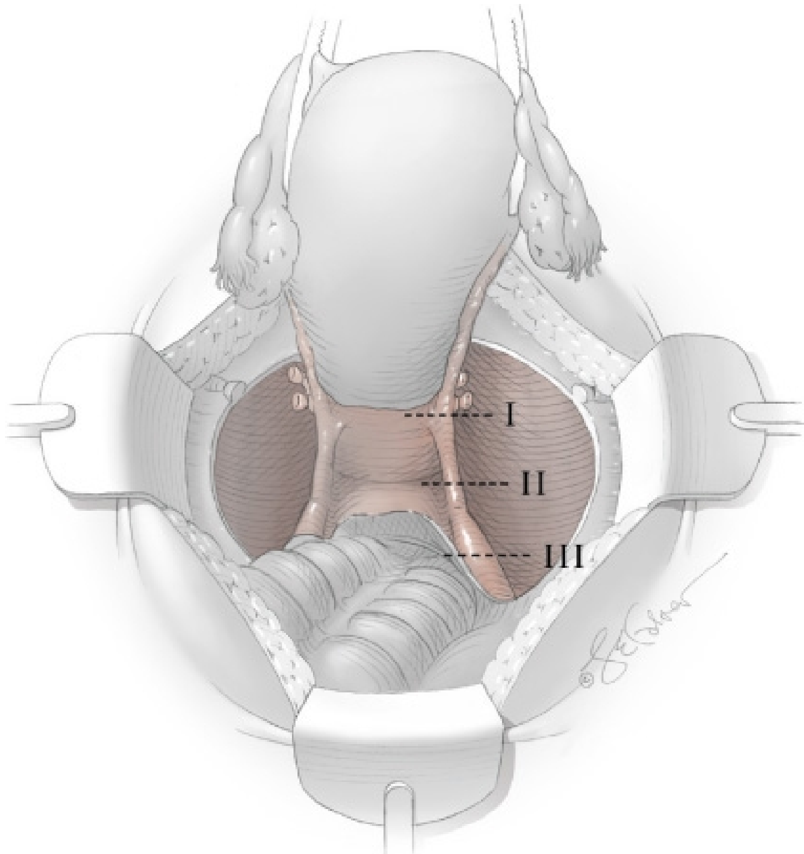


Source: Schorge JO, Schaffer JI, Halvorson LM, Hoffman BL, Bradshaw KD, Cunningham FG: *Williams Gynecology*: http://www.accessmedicine.com

Cardinal ligament resection.

6. **Uterosacral Resection.** Posterior dissection is also modified. Uterosacral ligaments are clamped halfway to the pelvic sidewall (instead of at the pelvic sidewall) and transected (Fig. 43-2.3). The uterus and adjacent parametrium then can be lifted well out of the pelvis, and any additional tissues also are clamped, cut, and ligated.

FIGURE 43-2.3



Source: Schorge JO, Schaffer JI, Halvorson LM, Hoffman BL, Bradshaw KD, Cunningham FG: *Williams Gynecology*: http://www.accessmedicine.com

Uterosacral resection.

7. **Vaginal Resection.** At this point in surgery, the modified radical hysterectomy specimen should be held in place only by the paracolpium and vagina. The bladder and ureters are further bluntly and sharply dissected free until at least 2 cm of upper vagina will be included in the specimen (instead of 3 to 4 cm). Curved clamps are placed across the lateral paracolpium and vagina. Tissue directly above the clamps are cut and suture ligated. The upper vagina then can be closed with a continuous running method using 0-gauge delayed-absorbable suture. The specimen should be examined carefully to ensure an adequate upper vaginal segment and grossly negative margins.

Postoperative

In general, postoperative care follows that for radical hysterectomy but with a lower incidence of complications (Magrina, 1995). Partial sympathetic and parasympathetic denervation should be much less extensive in a modified radical hysterectomy. Thus, bladder dysfunction is much less likely than following a type III radical hysterectomy, and successful voiding occurs much earlier (Landoni, 2001; Yang, 1999). Foley catheter drainage may be discontinued on the second postoperative day and followed by a voiding trial (see Chap. 39, Voiding Trials). In addition, bowel and sexual dysfunction also should be less pronounced.

43-3 TOTAL PELVIC EXENTERATION

Removal of the bladder, rectum, uterus (if present), and surrounding tissues is the most technically challenging single procedure in

gynecologic oncology. Total pelvic exenteration is indicated most commonly for centrally persistent or recurrent cervical cancer after radiation therapy (Berek, 2005; Goldberg, 2006). Less common indications include some instances of recurrent endometrial adenocarcinoma, uterine sarcoma, or vulvar cancer; locally advanced carcinoma of the cervix, vagina, or endometrium when radiation is contraindicated, such as previous radiotherapy or malignant fistula; and melanoma of the vagina or urethra (Barakat, 1999; Geisler, 1995; Kecmanovic, 2003; Miller, 1995a; Morley, 1989).

Total pelvic exenteration generally is indicated for curative situations such as when less radical surgery, chemotherapy, or radiation options have been exhausted. However, palliative exenterations may be of benefit on rare occasions when selected patients have severe, unrelenting symptoms (Brophy, 1994; Woodhouse, 1995). Because exenteration commonly follows radiation therapy, the uterus and cervix usually lose their distinct tissue architecture and boundaries. As a result, traditional hysterectomy steps and anatomic landmark identification typically are not possible.

Total pelvic exenterations are subclassified based on the extent of pelvic floor muscle and vulvar resection (Table 43-3.1) (Magrina, 1997). Supralevator (type I) exenteration may be indicated when a lesion is relatively small and does not involve the lower half of the vagina. Most total pelvic exenterations will be infralevator (type II). This type is selected if vaginal contracture, prior hysterectomy, or an inability to otherwise achieve adequate margins is present. Rarely, tumor extension warrants an infralevator exenteration with vulvectomy (type III).

Table 43-3.1 Differences among Type I (Supralevator), Type II (Infralevator), and Type III (with Vulvectomy) Pelvic Exenterations

	Degree of Resection		
Pelvic Structure	**Type I**	**Type II**	**Type III**
Viscera	Above levator	Below levator	Below levator
Levator ani muscles	None	Limited	Complete
Urogenital diaphragm	None	Limited	Complete
Vulvoperineal tissues	None	None	Complete

Mobilizing the bladder.

Preoperative

PATIENT EVALUATION

Initially, biopsy confirmation of recurrent invasive disease should be performed. With confirmation, the single most important preoperative challenge is to search for metastatic disease that would abort plans for surgery. Chest radiography is mandatory. Abdominal-pelvic computed tomographic (CT) scanning also is indicated routinely, but a positron-emission tomographic (PET) scan may be particularly helpful (Chung, 2007). Hydroureter and hydronephrosis are not absolute contraindications unless they are due to obvious pelvic sidewall disease.

Patients often reject the entire concept of this operation initially even when faced with the knowledge that it represents their only chance for cure. Counseling is essential. Overcoming denial may take several visits. Regardless, not all eligible women will wish to proceed.

Pre-existing medical problems, morbid obesity, and malnutrition increase the potential morbidity of total pelvic exenteration. Thus, a surgeon should take all factors into consideration and candidly explore all possible alternatives before proceeding with surgical planning.

CONSENT

The consenting process is the ideal time to finalize plans for the type and location of urinary conduit, plans for colostomy or low rectal anastomoses, and need for vaginal reconstruction or other ancillary procedures. The patient also should be advised that the procedure may need to be aborted based on intraoperative findings (Miller, 1993).

For those who undergo exenteration, perioperative mortality approaches 5 percent (Dottino, 1995; Sharma, 2005). However, the mortality from progressive cancer otherwise would be 100 percent. Patients should be prepared for admission to an intensive care unit (ICU) postoperatively. Febrile morbidity, wound breakdown, bowel obstruction, and venous thromboembolic events are common short-term complications. Additionally, intestinal fistulas or anastomotic leaks or strictures may develop. Most women will experience significant morbidity and unforeseen complications (Goldberg, 2006). Re-operation may be required.

Long-term effects on sexual function and other body functions should be reviewed candidly. Patients with two ostomies have a lower quality of life and poorer body image. However, in those who retain vaginal capacity, quality of life and sexual function reportedly may be preserved. A detailed approach to the consent process can help to resolve many of these dilemmas and achieve the ideal balance for an individual patient (Hawighorst, 2004; Roos, 2004). In general, a woman's postoperative quality of life is most affected by her worries about tumor progression (Hawighorst-Knapstein, 1997). Therefore, patients should be aware that up to half will develop recurrent disease despite exenterative surgery (Goldberg, 2006; Sharma, 2005).

PATIENT PREPARATION

Patients often are admitted the day before surgery to aid important preoperative planning. Stoma sites are marked, the consent form is re-reviewed, and final questions answered.

To minimize fecal contamination during bowel excision, aggressive bowel preparation such as with a polyethylene glycol with electrolyte solution (GoLYTELY) is mandatory. Ileus is common following exenteration, and nutritional demands are increased. Thus, total parenteral nutrition may be initiated. In addition, routine antibiotic prophylaxis has been shown to decrease infectious complications (Goldberg, 1998). Pneumatic compression devices or subcutaneous heparin is particularly important owing to the anticipated length of the operation and longer duration of postoperative recovery (see Chap. 39, Prophylaxis Options). Patients should be typed and crossed for potential packed red blood cell replacement (see Chap. 40, RBC Replacement). Critical care team consultation may be indicated, and an ICU bed should be requested.

Intraoperative

INSTRUMENTS

To prepare for complicated resections, the surgeon should have access to all types and sizes of bowel staplers, which include end-to-end anastomosis (EEA), gastrointestinal anastomosis (GIA), and transverseanastomosis (TA) staplers. Additionally, a ligate-divide-staple (LDS) device may be used for vessel ligation.

Surgical Steps

1. **Anesthesia and Patient Positioning.** General anesthesia with or without epidural placement for postoperative pain management is mandatory. Invasive monitoring typically is added as a necessary precaution. Bimanual examination should be performed to re-orient the surgeon to specific patient anatomy. The abdomen, perineum, and vagina are surgically prepared, and a Foley catheter is inserted. Legs should be positioned in a low lithotomy position in Allen stirrups to permit adequate perineal access.

2. **Abdominal Entry.** The type of abdominal entry may be dictated by an intended rectus abdominis flap, but otherwise a midline vertical incision is ideal (see Section 41-1, Midline Vertical Incision). A less commonly employed option is to assess patients initially by laparoscopy. This minimally invasive approach may avoid unnecessary laparotomy in up to half of patients (Kohler, 2002; Plante, 1998).

3. **Exploration.** The most common reason that exenterations are aborted is the presence of metastatic peritoneal disease (Miller, 1993). Thus, following positioning of an abdominal self-retaining retractor, the surgeon should explore thoroughly for disseminated disease that is often not detected preoperatively. Typically, numerous adhesions also must be lysed to inspect and palpate abdominal contents. Suspicious lesions should be removed or biopsied.

4. **Lymph Node Dissection.** Approximately 40 percent of exenterations will be aborted intraoperatively due to identification of lymph node metastasis (Miller, 1993). For this reason, pelvic and para-aortic node sampling is performed to exclude metastatic disease before proceeding (see Sections 43-9, Pelvic Lymphadenectomy and 43-10, Para-Aortic Lymphadenectomy). Additionally, dissection provides a surgeon with a sense of the degree of pelvic retroperitoneal fibrosis.

5. **Pelvic Sidewall Exploration.** As described in Section 43-1, Radical Abdominal Hysterectomy (Type III) (Steps 4-6), the external iliac and internal iliac artery bifurcation is bluntly dissected free of overlying areolar connective tissue, and the ureter is placed on a Penrose drain for identification. The paravesical and pararectal spaces are developed.

   Parametrial tumor extension is the third most common reason for aborting exenteration (Miller, 1993). Thus, the pelvic sidewall should be verified to be clinically free of disease by inserting one finger into the paravesical space, another into the pararectal space, and palpating the intervening tissue down to the levator plane. There must be a grossly negative margin at the pelvic sidewall to proceed. Tissues may be biopsied and sent for frozen-section analysis to confirm this impression.

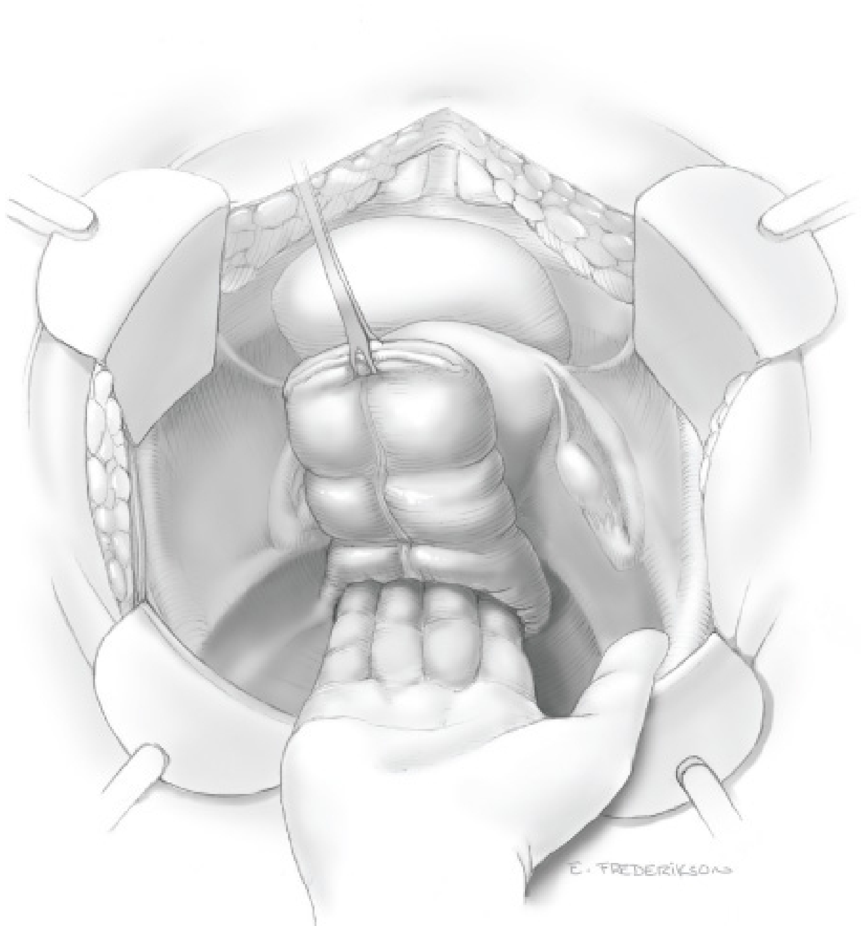
6. **Bladder Mobilization.** The bladder blade is removed from the self-retaining retractor to permit entry into the space of Retzius and blunt reflection of the bladder from the back of the pubic symphysis. Downward traction on the bladder and urethra will expose filmy attachments that may be incised electrosurgically (Fig. 43-3.1). Laterally positioned false ligaments of the bladder are divided between clamps, and this joins the retropubic and paravesical spaces. The bladder should be floppy in the pelvis from loss of its supporting pelvic attachments and completely freed anteriorly. However, the urethra is still attached to the bladder.

7. **Rectum Mobilization.** Following mobilization of the bladder, the ureters are held laterally, and the overlying peritoneum at the pelvic brim is divided in a medial direction up to the sigmoid mesentery. By inserting a finger into the pararectal space and sweeping medially, it should be possible to develop the avascular plane between the rectosigmoid and the sacrum (retrorectal space).

   Surgeons should be confident that there is no sacral tumor invasion and that they will be able to lift the rectosigmoid out of the pelvis to achieve a posterior margin that is free of tumor. This is the last decision to be made before dividing the bowel and beginning steps of the operation that are irreversible.

   Once the entire circumference of the tumor has been assessed, exenteration proceeds by dividing the sigmoid with a gastrointestinal anastomotic (GIA) stapler and dividing the intervening mesenteric tissue (see Section 43-19, Low Anterior Resection). This stapler lays two rows of staples and transects the interposed bowel. The proximal sigmoid then is packed into the upper abdomen. The distal rectosigmoid is held ventrally and cephalad while a hand is inserted posteriorly to bluntly dissect the adventitial tissue between the rectum and sacrum in the midline (Fig. 43-3.2). This maneuver is continued distally to the coccyx to develop the retrorectal space and isolate the laterally located rectal pillars.

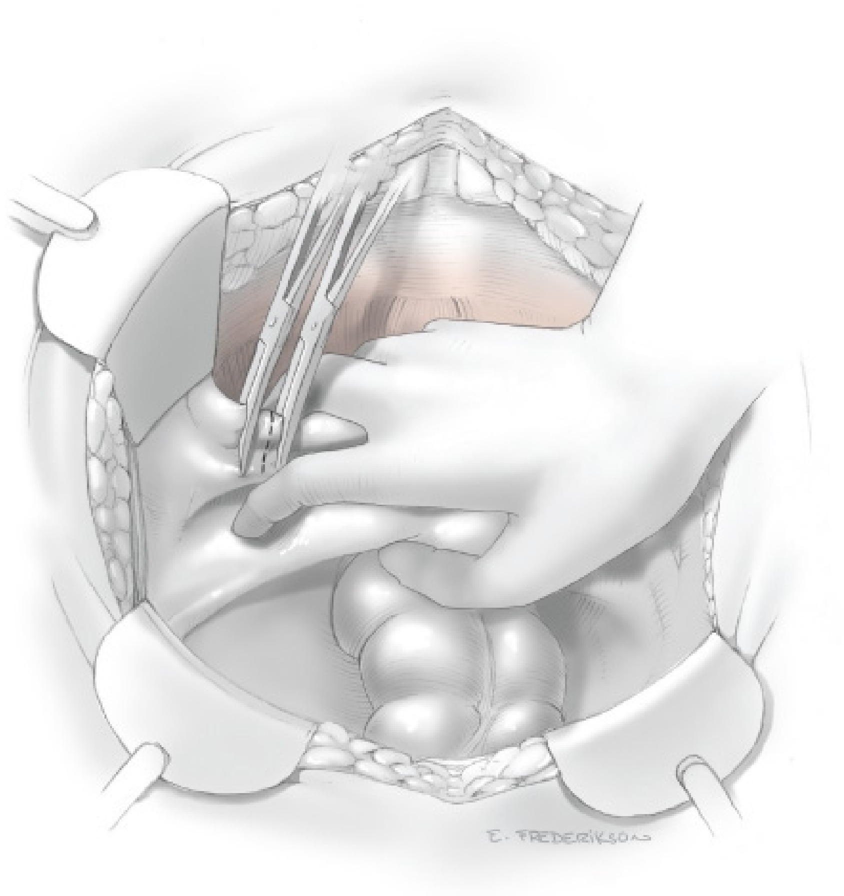
FIGURE 43-3.2



Mobilizing the rectum.

8. **Cardinal Ligaments Division.** The mobilized bladder and distal rectum with uterus (if present) are held together on contralateral traction to the incoming clamp while a hand is placed with one finger in the paravesical space and the other in the pararectal space to isolate the lateral pelvic attachments. The cardinal ligaments, internal iliac vessels, and ureter often are not distinguishable in a typically radiated field but lie within this tissue. Beginning anteriorly, these fibrous attachments are serially clamped, cut, and tied at the pelvic sidewall (Fig. 43-3.3). Vascular clips should be available in case of tissue slippage or inadvertent bleeding.

FIGURE 43-3.3



Source: Schorge JO, Schaffer JI, Halvorson LM, Hoffman BL, Bradshaw KD, Cunningham FG: *Williams Gynecology*: http://www.accessmedicine.com

Dividing the cardinal ligaments.

9. **Internal Iliac Vessels and Ureter Division.** As the pelvic sidewall clamping continues posteriorly along the levator muscles, the anterior branches of the internal iliac artery, venous channels, and the distal ureter ideally are individually located and ligated. However, blood vessels and ureters frequently will lie within fibrous tissue and will be relatively indistinguishable. Thus, clamps should be placed around smaller pedicles to minimize the possibility of inadvertent blood loss. At minimum, the ureter should be located, isolated, and divided. A large vascular clip is placed on its proximal end to distend the ureter and aid anastomosis into the planned conduit. Dissection then is repeated on the contralateral side, and any remaining lateral attachments along the levator ani muscles are divided as the pelvic floor curves toward the perineum (Fig. 43-3.4).

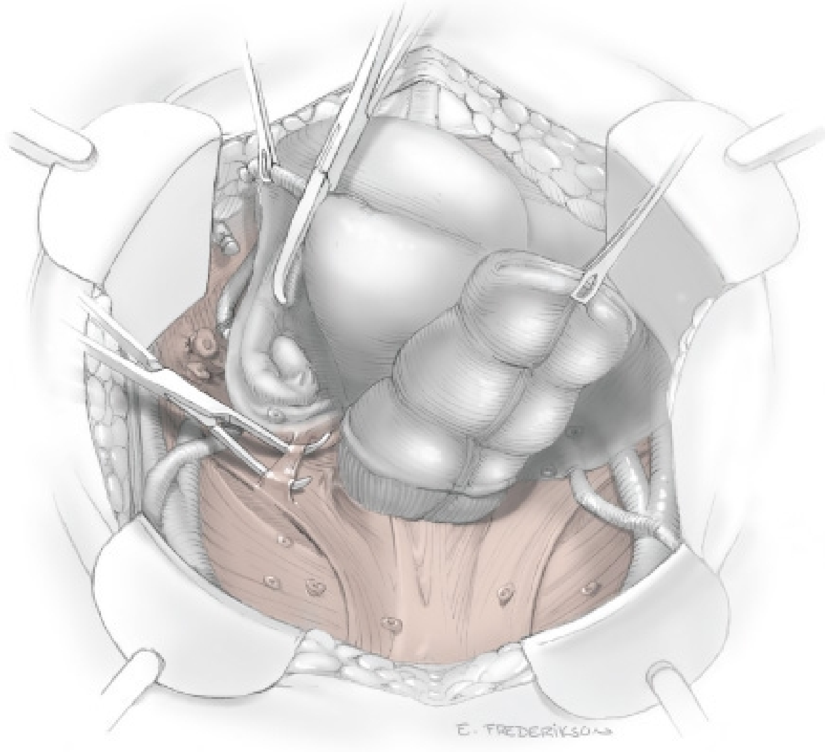
Dividing the hypogastric vessels and ureter.

10. **Rectal Pillar Division.** The exenteration specimen now is chiefly tethered by the rectal stalks and distal mesenteric attachments posteriorly. These can be isolated with a right-angle clamp and divided along the pelvic floor (Fig. 43-3.5). This maneuver is continued distally to expose the entire posterior pelvic floor. The exenteration specimen then is inspected circumferentially, and additional dissection is performed to completely release it from all attachments leading through the levator ani muscles.

FIGURE 43-3.5



Source: Schorge JO, Schaffer JI, Halvorson LM, Hoffman BL, Bradshaw KD, Cunningham FG: *Williams Gynecology*: http://www.accessmedicine.com

Dividing the rectal pillars.

11. **Supralevator Exenteration: Final Steps.** Removal of the specimen above the levator muscles begins by posterior traction on the bladder. The Foley catheter should be palpable within the urethra, and all surrounding tissue already should be dissected away. An electrosurgical blade is used to transect the distal urethra (Fig. 43-3.6). The distal opening does not require closure and may act as a drain postoperatively. The vagina then is transected and closed with delayed-absorbable suture in a running fashion. The transverse anastomosis (TA) stapler is placed across the distal rectum and fired. This stapler places one row of staples but does not transected tissue following application of the staple line. Therefore, a surgeon must sharply cut above the staple line to separate proximal and distal bowel segments. This completes detachment of the specimen, which includes bladder, uterus, rectum, and surrounding tissue (Fig. 43-3.7). The pelvic floor then is assessed carefully to identify bleeding points (Fig. 43-3.8). A laparotomy pad is packed firmly into the pelvis to tamponade any surface that is oozing while the exenteration specimen is inspected to confirm grossly negative margins.

Supralevator exenteration: appearance of the pelvic floor.

12. **Infralevator Exenteration: Perineal Phase.** When the abdominal dissection reaches the levator muscles, a second surgical team begins the perineal phase. The use of two teams typically shortens operative time and reduces bleeding. The planned perineal resection is outlined to encompass the tumor. As shown in Fig. 43-3.9, resection may require infralevator exenteration without vulvectomy or infralevator exenteration with vulvectomy.

    The perineal incision ideally begins concomitantly with division of the levator muscles by the abdominal team. An electrosurgical blade is used to dissect around the urethra, vaginal opening, and anus.

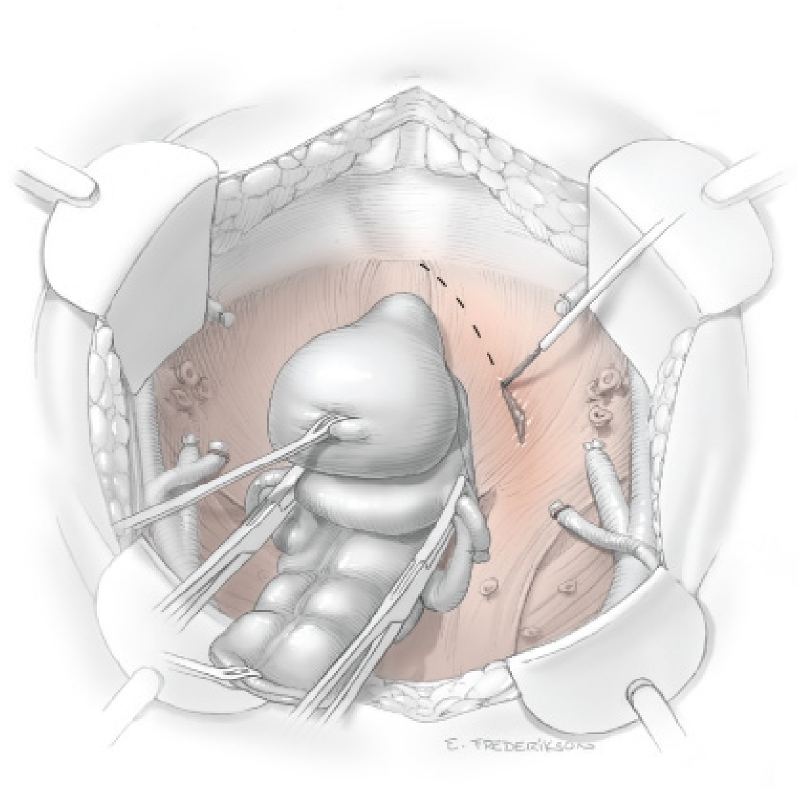
FIGURE 43-3.9

Source: Schorge JO, Schaffer JI, Halvorson LM, Hoffman BL, Bradshaw KD, Cunningham FG: *Williams Gynecology*: http://www.accessmedicine.com

Infralevator exenteration: perineal phase incisions.

13. **Infralevator Exenteration: Partial Resection of the Levator Muscles.** Within the abdomen, the primary surgical team places the specimen on traction. Electrosurgical blade dissection is used to incise the levator ani muscles circumferentially lateral to the area of tumor extension (Fig. 43-3.10). The dissection proceeds distally toward the perineum.

FIGURE 43-3.10



Source: Schorge JO, Schaffer JI, Halvorson LM, Hoffman BL, Bradshaw KD, Cunningham FG: *Williams Gynecology*: http://www.accessmedicine.com

Infralevator exenteration: partial resection of the levator muscles.

14. **Infralevator Exenteration: Connecting the Perineal and Abdominal Spaces.** After the perineal incision has reached the fascial plane, four spaces are developed: subpubic space, left and right vaginal spaces, and retrorectal space. It is helpful to have the abdominal surgeon place a hand deep into the pelvis to guide the electrosurgical dissection by the perineal team (Fig. 43-3.11). Five pedicles should be identified that separate these avascular spaces: two pubourethral, two rectal pillar, and the midline posterior anococcygeal. Electrosurgical dissection that is directed by the abdominal surgeon's finger is performed to open the spaces. From below, clamps then are placed on the intervening five vascular pedicles, which then may be divided and ligated.

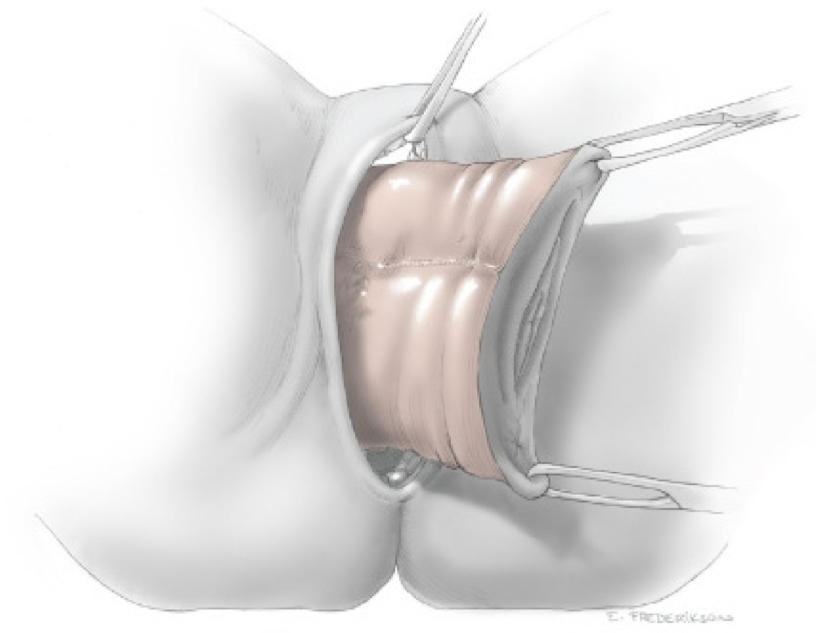
FIGURE 43-3.11

Source: Schorge JO, Schaffer JI, Halvorson LM, Hoffman BL, Bradshaw KD, Cunningham FG: *Williams Gynecology*: http://www.accessmedicine.com

Infralevator exenteration: connecting the perineal and abdominal spaces.

15. **Infralevator Exenteration: Removal of the Specimen.** Circumferential dissection will result in complete detachment of the specimen, which can be removed either vaginally or abdominally (Fig. 43-3.12). Hemostasis then is achieved with a series of sutures, vascular clips, or clamps and ties. The pelvic floor is inspected carefully and pedicle sites reviewed (Fig. 43-3.13).

FIGURE 43-3.12



Source: Schorge JO, Schaffer JI, Halvorson LM, Hoffman BL, Bradshaw KD, Cunningham FG: *Williams Gynecology*: http://www.accessmedicine.com

Infralevator exenteration: pelvic floor.

16. **Infralevator Exenteration: Simple Closure.** The most straightforward and quickest way to close the perineum is for the second team to perform a layered closure of the deep tissues with delayed-absorbable suture (Fig. 43-3.14).

    The perineal skin is closed with a delayed-absorbable suture in a running fashion.

FIGURE 43-3.14

Source: Schorge JO, Schaffer JI, Halvorson LM, Hoffman BL, Bradshaw KD, Cunningham FG: *Williams Gynecology*: http://www.accessmedicine.com

Infralevator exenteration: simple perineal closure.

17. **Final Steps.** A dry laparotomy pad may be held firmly deep in the pelvis to tamponade surface oozing while the conduit, colostomy or bowel anastomosis, and other surgical procedures are performed. An omental J-flap may provide additional blood supply to the irradiated, denuded pelvic floor (see Section 43-8, Vaginal Reconstruction). The type of postoperative suction drainage may be dictated by these ancillary procedures but should be used judiciously (Goldberg, 2006).

Postoperative

The morbidity of total pelvic exenteration depends on a variety of factors: preoperative health of the patient, intraoperative events, extent of the procedure, ancillary procedures, and postoperative vigilance. Hospitals that treat a relatively high volume of such patients report lower surgical in-hospital mortality rates (Begg, 1998).

The immediately life-threatening concerns are massive bleeding, adult respiratory distress syndrome, pulmonary embolism, and myocardial infarction (Dottino, 1995; Finan, 1996; Wydra, 2006). Every effort should be made to encourage early ambulation as soon as the patient is stabilized. A prolonged ileus or small bowel obstruction typically will respond to expectant management but may require initiation of total parenteral nutrition. Intestinal fistulas and leaks are more common when using mesh to cover the pelvic floor or when performing low rectal anastomoses. Omental pedicle grafts and rectus abdominis or gracilis myocutaneous flaps may prevent such complications (see Section 43-8, Vaginal Reconstruction) (Goldberg, 2006; Miller, 1995b). Pelvic abscess and septicemia are additional subacute complications that occur commonly.

43-4 ANTERIOR PELVIC EXENTERATION

Removal of the uterus, vagina, bladder, urethra, distal ureters, and parametrial tissues with preservation of the rectum is meant to be a less morbid operation than total pelvic exenteration. Patients need to be very carefully selected for this more limited procedure to still achieve negative margins. For this reason, women who have previously had a hysterectomy usually are not good candidates.

The most common indications include small recurrences confined to the cervix or anterior vagina after pelvic radiation. In gynecologic oncology, approximately 15 percent of exenterations are anterior (Crozier, 1995; Morley, 1989).

Preoperative

The preoperative evaluation is similar to that described for total pelvic exenteration (see Section 43-3, Total Pelvic Exenteration). Although preservation of the rectum is planned, patients should be advised during the consenting process that potentially unforeseen clinical circumstances may dictate bowel resection and colostomy or low rectal anastomosis. Accordingly, a complete bowel preparation is mandatory.

Intraoperative

Surgical Steps

1. **Initial Steps.** Anterior exenteration is technically similar to total pelvic exenteration, described earlier. Patients are positioned in Allen stirrups, the appropriate skin incision is made, the abdomen is explored, lymph nodes are removed, and spaces are developed to exclude metastatic or unresectable disease (see Section 43-3, Total Pelvic Exenteration, Steps 1-5). The procedure begins to differ after the bladder has been mobilized. The surgeon then decides to leave the rectum intact and proceed with anterior pelvic exenteration.

2. **Developing the Rectovaginal Space.** Instead of mobilizing the rectum and dividing the sigmoid, the rectovaginal space is developed much like in a type III radical hysterectomy (see Section 43-1, Radical Abdominal Hysterectomy (Type III), Step 12). The uterosacral ligament and the entire length of the rectal pillars are divided to free the exenteration specimen posteriorly (see Fig. 43-1.7).

3. **Lateral Pelvic Attachments.** The mobilized bladder and uterus are held medially to aid isolation of the cardinal ligaments, internal iliac vessels, and ureter. These structures are successively clamped, cut, and individually ligated (see Section 43-3, Total Pelvic Exenteration, Steps 8-9).

4. **Removal of the Specimen.** After the anterior pelvic exenteration specimen has been mobilized completely, the urethra and vagina are divided (Fig. 43-4.1). The vaginal cuff is closed with delayed-absorbable suture in a running fashion (Fig. 43-4.2). Similarly, the urethra is closed with a running suture using delayed-absorbable suture. Creation of a urinary conduit follows as described in Section 43-6, Incontinent Urinary Conduit and 43-7, Continent Urinary Conduit.

FIGURE 43-4.1

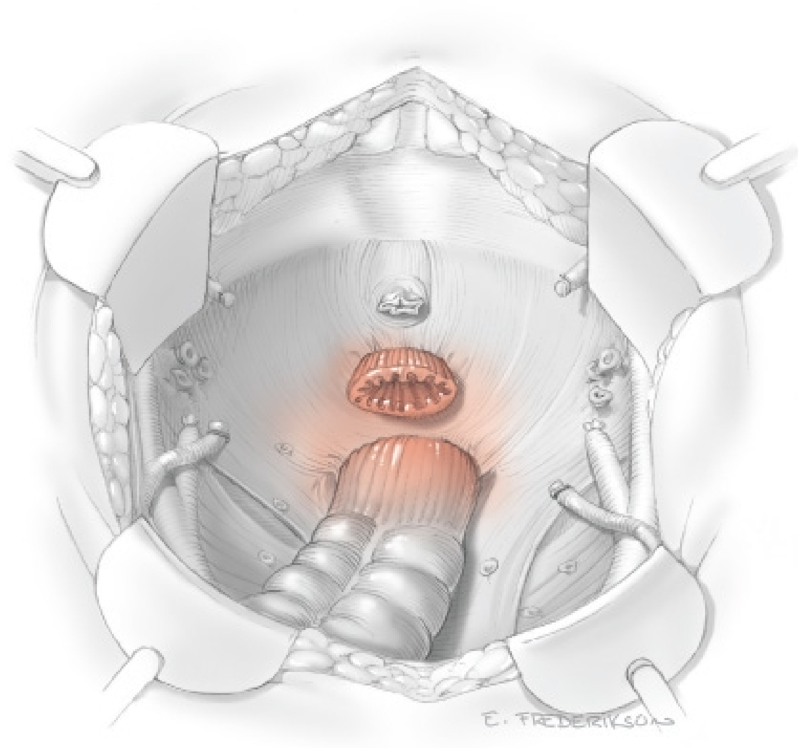
Removal of the specimen.

FIGURE 43-4.2



Source: Schorge JO, Schaffer JI, Halvorson LM, Hoffman BL, Bradshaw KD, Cunningham FG: *Williams Gynecology*: http://www.accessmedicine.com

Appearance of the pelvic floor.

5. **Final Steps.** Typically, the lesion is small and lies above the levators; thus, a perineal phase is not required. Placement of a myocutaneous flap for vaginal reconstruction may be more problematic in these patients due to limited space in the pelvis.

Postoperative

Morbidity of anterior pelvic exenteration is comparable with that for total pelvic exenteration (Sharma, 2005). Ideally, the operation is shorter, and restoration of bowel function is more rapid. Some patients will experience tenesmus or long-term rectal symptoms that likely stem from interruption of the autonomic nervous system in surrounding tissue.

43-5 POSTERIOR PELVIC EXENTERATION

Removal of the uterus, vagina, rectum, and parametrial tissues with preservation of the ureters and bladder is meant to be a less morbid operation than total pelvic exenteration. Patients should be selected carefully for this more limited procedure to still achieve negative margins. For this reason, women who have previously had a hysterectomy usually are not good candidates. The most common indications include small postirradiation recurrences involving primarily the posterior vaginal wall or co-existing with a rectovaginal fistula. In gynecologic oncology, fewer than 10 percent of exenterations are posterior (Berek, 2005; Crozier, 1995).

Preoperative

Preoperative evaluation is largely identical to that described for total pelvic exenteration (see Section 43-3, Total Pelvic

Exenteration). The surgeon's judgment and experience are critical in deciding to proceed with a more limited operation. However, patients should be advised during the consenting process that potentially unforeseen clinical circumstances may dictate resection of the ureters and bladder with formation of a urinary conduit (see Sections 43-6, Incontinent Urinary Conduit and 43-7, Continent Urinary Conduit).

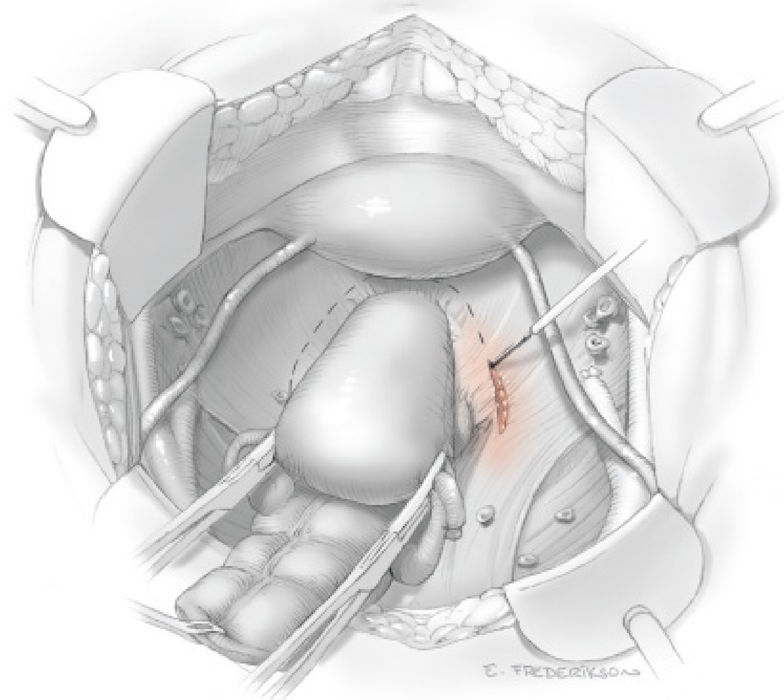
Intraoperative

Surgical Steps

1. **Initial Steps.** Posterior pelvic exenteration is technically similar to a type III radical hysterectomy but with the addition of a more extended vaginectomy and rectosigmoid resection (see Section 43-1, Radical Abdominal Hysterectomy (Type III)). The operation begins as a total pelvic exenteration. Patients are positioned in Allen stirrups, the appropriate skin incision is made, the abdomen is explored, lymph nodes are removed, and spaces are developed to exclude metastatic or unresectable disease (see Section 43-3, Total Pelvic Exenteration, Steps 1-5). The surgeon then decides whether to leave the bladder intact and proceed with posterior exenteration.

2. **Ureteral Dissection.** The ureters are mobilized, uterine arteries are ligated at their internal iliac origin, and parametrial tissue is divided at the pelvic sidewall (see Section 43-1, Radical Abdominal Hysterectomy (Type III), Steps 4-8). The bladder then is dissected distally to aid in unroofing the ureters from the parcervical tunnels much like in a type III radical hysterectomy (see Section 43-1, Radical Abdominal Hysterectomy (Type III), Steps 9-11). The lateral attachments have been clamped, cut, and tied with delayed-absorbable suture all the way to the levator ani muscles (Fig. 43-5.1). However, typically these steps are more tedious in a previously irradiated field because of tissue fibrosis and scarring.

FIGURE 43-5.1



Source: Schorge JO, Schaffer JI, Halvorson LM, Hoffman BL, Bradshaw KD, Cunningham FG: *Williams Gynecology*: http://www.accessmedicine.com

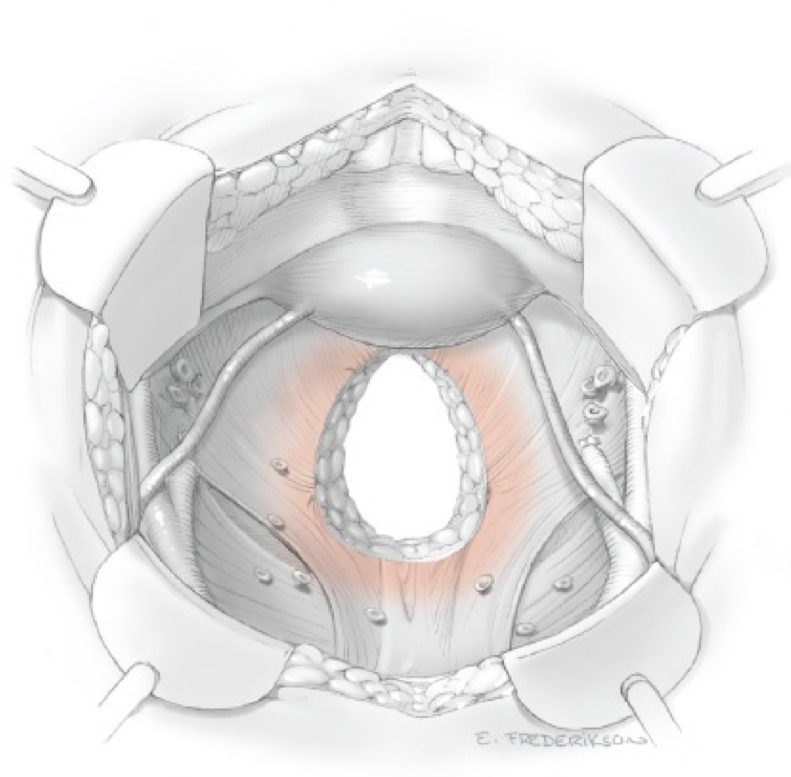
Incising the levator muscles.

3. **Mobilizing the Rectum.** The sigmoid is divided with the mesentery and peritoneal attachments, as described earlier for a total pelvic exenteration (see Section 43-3, Total Pelvic Exenteration, Step 7). The retrorectal space is dissected bluntly to mobilize the rectum and enable transection of the rectal pillars (see Fig. 43-3.5).

4. **Removal of the Specimen.** The dissection is continued circumferentially to (or through) the levator ani muscles to encompass the tumor (Fig. 43-5.2).

   The distal vagina is transected and sewn closed. The entire specimen then may be placed on traction to aid placement of the transverse anastomosis (TA) stapler and division of the rectum. The rectum is divided below the tumor, and the specimen is removed.

FIGURE 43-5.2



Source: Schorge JO, Schaffer JI, Halvorson LM, Hoffman BL, Bradshaw KD, Cunningham FG: *Williams Gynecology*: http://www.accessmedicine.com

Specimen removed.

5. **Final Steps.** Typically, the lesion is small and lies above the levator ani muscles. Thus, for these cases, a perineal phase is not required. Placement of a myocutaneous flap for vaginal reconstruction may be more problematic in such patients due to limited space in the pelvis. The sigmoid colon is removed from the upper abdomen, and colostomy or rectosigmoid anastomosis is completed.

Postoperative

Morbidity of posterior pelvic exenteration is comparable with that of total pelvic exenteration (Sharma, 2005). Ideally, the operation is shorter and urinary complications are less frequent. However, posterior exenteration in a previously irradiated patient frequently results in a contracted bladder and intractable urinary incontinence.

43-6 INCONTINENT URINARY CONDUIT

Removal of the bladder during total or anterior exenteration is the main indication for an incontinent urinary conduit. Less commonly, an otherwise irreparable postirradiation vesicovaginal fistula may warrant urinary diversion. Following cystectomy, a resected segment of bowel that maintains its mesenteric and vascular connections is used as a new reservoir. A stoma is crafted between the bowel segment and an opening in the anterior abdominal wall. Ureters are re-implanted into this portion of bowel.

Various diversion techniques are available to create such urinary conduits. These are categorized as *incontinent diversions or continent diversions.* Incontinent diversion is the simplest to create, but postoperatively, a patient must wear an ostomy bag continuously. These conduits often are preferable for medically compromised patients, the elderly, and anyone with a short life expectancy. Alternatively, a continent urinary reservoir can be created that is emptied by intermittent patient self-catheterization of the bowel stoma.

Of incontinent diversions, an *ileal conduit* historically has been the most common urinary diversion used in gynecologic oncology (Orr, 1982b). However, the bowel segment and distal ureters invariably lie within the radiated field, which may lead to higher rates of stenosis or leakage at the ureteral anastomotic sites. More recently, *the transverse colon conduit* has proven to be a very successful alternative for previously irradiated patients (Segreti, 1996a; Soper, 1989). *Sigmoid conduits* generally are less desirable owing to pre-existing radiation damage and proximity to a colostomy site. The *jejunal conduit* is another rarely used option outside the radiation field. In these patients, the shortest possible segment should be used to decrease the characteristic electrolytic syndrome of hypochloremic acidosis with hyponatremia, hyperkalemia, and uremia (Golimbu, 1975; Klein, 1986).

The basic principles of constructing an incontinent urinary conduit are the sameâ€"regardless of the intestinal segment used. First, healthy-appearing bowel should be selected with a good blood supply. Second, wide ureterointestinal anastomoses and stenting are essential to minimize the risk of stenosis. Third, sufficient mobility of the ureters and bowel segment is important to prevent any tension that might lead to anastomotic leaks. Fourth, creation of a straight tunnel through the abdominal wall will prevent obstruction.

Preoperative

PATIENT EVALUATION

The preoperative evaluation usually is dictated by the preceding exenterative procedure. The specific decision is whether to plan for an incontinent or continent urinary conduit. Patients should be counseled extensively about the differences. The type of conduit selected should be considered permanent, although later conversions are possible (Benezra, 2004).

CONSENT

Patients should be advised that intraoperative findings may dictate revision of an original surgical plan. Postoperatively, urinary infections with or without pyelonephritis are common. Anastomotic leaks are less frequent with routine ureteral stent placement but are potentially problematic (Beddoe, 1987). Episodes of small bowel obstruction are possible. In the long term, strictures and stenoses may cause renal compromise. Infrequently, re-operation is necessary for complications that do not respond to conservative management (Houvenaeghel, 2004).

PATIENT PREPARATION

Bowel preparation obviously is mandatory, but preparation typically is dictated by the preceding exenterative surgery. Ideally, an enterostomal therapist is available to mark a conduit stoma site. This site should be unobstructed in the supine, sitting, and standing positions.

Intraoperative

Surgical Steps

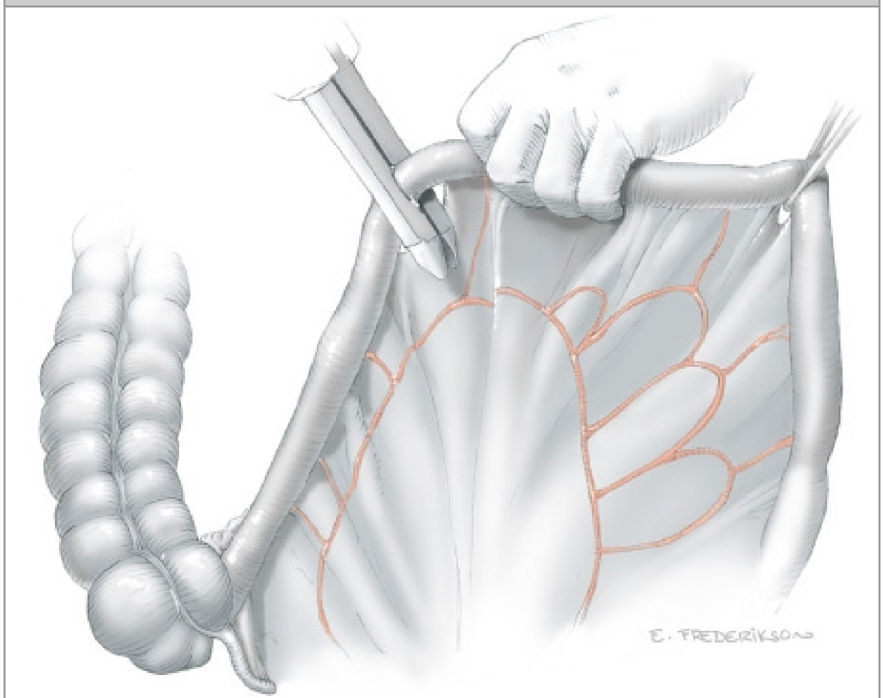
1. **Initial Steps.** The incontinent urinary conduit is constructed as the last major intra-abdominal procedure during exenterative surgery to avoid unnecessary traction on the anastomoses. Hemostasis should be achieved before beginning the conduit. Anesthesia requirements, patient positioning, and skin incisions typically are dictated by the preceding operation.

2. **Exploration.** The bowel segment should be inspected carefully at the planned conduit site. It must be healthy appearing, not tethered, and lie within range of the distal ureters. The final decision now is made about which type of incontinent conduit is best for the circumstances. If the distal ileum has the typical leathery, pale, mottled appearance of radiation injury, a conduit should be prepared from the transverse colon. Overlooking the importance of this decision can lead to a variety of otherwise preventable complications intraoperatively and postoperatively.

3. **Ileal Conduit: Preparing the Bowel Segment.** The ileocecal junction is located, and the ileum is elevated proximally. A bowel section is identified with the most mobility to reach the right side of the abdominal wall where the stoma will be located. Ideally, this section begins 25 to 30 cm from the ileocecal valve. The mesentery is scored with an electrosurgical blade on each side at this point to aid insertion of a hemostat directly beneath the ileal serosa. A Penrose drain is pulled through to mark the section of bowel that will become the abdominal wall stoma.

   The conduit length depends on subcutaneous tissue depth and ileum mobility but should measure approximately 15 cm. The conduit's proximal end is selected by measuring the ileum that lies distal to the Penrose drain, and again, the mesentery is scored. The gastrointestinal anastomosis (GIA) stapler then is inserted to divide the distal bowel segment (Fig. 43-6.1). The point of division ideally should be at least 12 cm from the ileocecal valve. Intestinal continuity, minus the excised segment, is re-established anterior to the conduit with a functional end-to-end anastomosis using the GIA and transverse anastomosis (TA) staplers (see Figs. 43-18.2 and 43-18.3). The conduit mesentery is divided carefully. The vasculature may be compromised if too much mesentery is divided, whereas too little will result in tension on the conduit. A perfect balance is required.

FIGURE 43-6.1



Source: Schorge JO, Schaffer JI, Halvorson LM, Hoffman BL, Bradshaw KD, Cunningham FG: *Williams Gynecology*: http://www.accessmedicine.com

Ileal conduit: preparing the bowel segment.

4. **Ileal Conduit: Preparing the Ureters.** The staple line is excised from the stomal end of the conduit, and the conduit is irrigated. The ureters should be engorged from clips placed earlier during exenteration (see Section 43-3, Total Pelvic Exenteration, Step 9). The distal end of the ureters never should be grasped directly with forceps or handled roughly to prevent focal necrosis that may impede successful anastomosis. They are freed from their retroperitoneal attachments so that they easily reach past the point of their planned anastomosis into the conduit.

5. **Ileal Conduit: Ureteral Anastomoses.** Adson forceps are used to grasp a small section of the ileal serosa where the left ureter will reachâ€"ideally approximately 2 cm from the proximal conduit's end on the anterior side of the antimesenteric

surface. At this site, Metzenbaum scissors remove a small full-thickness section of bowel wall (Fig. 43-6.2). The ileal mucosa should be easily visible.

The distal tip of the left ureter is cut at a 45-degree angle just in front of the previously placed clip. If the distal ureters exhibit fibrosis, they are trimmed to reach healthy tissue. Urine will drain into the abdomen while a 4-0 delayed-absorbable stay suture is placed from outside through the ureter's distal tip. The needle is left on this traction stitch because it will be the final suture in the anastomosis. Fine-tip scissors are used to spatulate the ureter for 1 cm (Fig. 43-6.3). This maneuver may reduce the possibility of future stenosis.

The first suture is placed at the apex of the spatulation with a full-thickness bite through the ureteral wall and bowel mucosa (Fig. 43-6.4). Two or three additional sutures are placed. The ileal mucosa must be included in each stitch for best results. A 6F or 7F ureteral stent then is placed through the stoma and advanced through the anastomosis into the left renal pelvis. This is held against the wall of the conduit with one hand and secured with a 3-0 or 4-0 plain catgut suture through the entire bowel wall around the stent to hold it in place. The left ureteral anastomosis is completed with additional sutures.

The entire procedure then is repeated on the right. Saline with methylene blue dye may be used to fill the conduit and observe for anastomotic leaks.

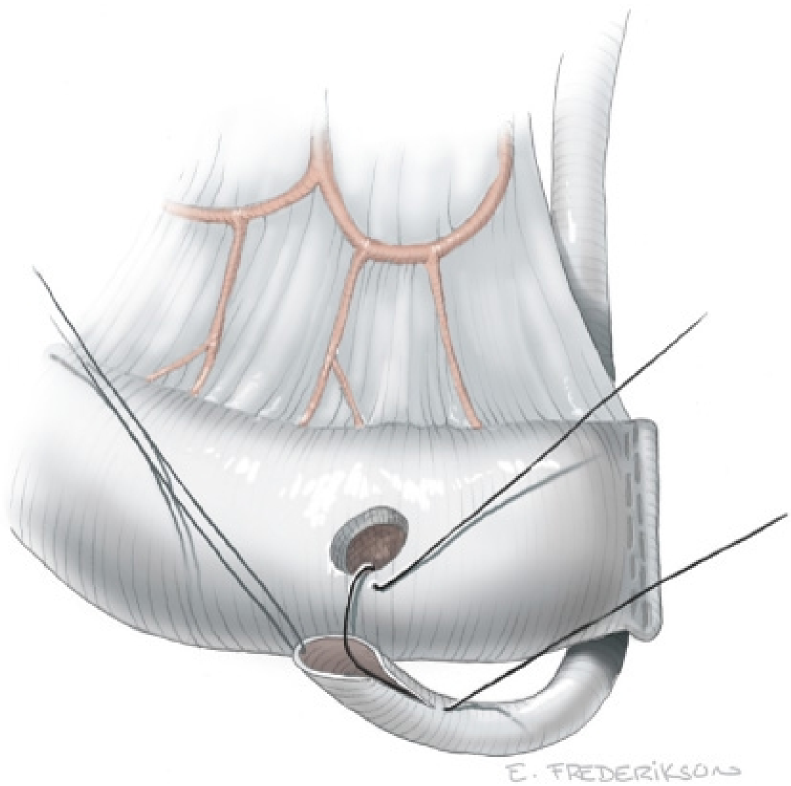
FIGURE 43-6.4



Source: Schorge JO, Schaffer JI, Halvorson LM, Hoffman BL, Bradshaw KD, Cunningham FG: *Williams Gynecology*: http://www.accessmedicine.com

Ileal conduit: suturing ureter and ileal segment.

6. **Ileal Conduit: Stoma Creation.** The skin at the proposed stoma site is elevated with a Kocher clamp. An electrosurgical blade, set on cutting mode, is used to excise a small circle of skin. The subcutaneous fat is separated by blunt dissection until the fascia is visible. A cruciate incision is made with an electrosurgical blade (Fig. 43-6.5). The rectus abdominis muscle is split longitudinally, and another cruciate incision is created in the peritoneum. The opening is expanded bluntly until it easily accommodates two fingers.

   The proximal conduit and stents are carefully pulled through the incision until at least 2 cm of ileum protrudes through the skin (Fig. 43-6.6). The mesentery may need to be trimmed or the abdominal wall opening further dissected to accommodate the conduit. The mucosal edge is everted. The stoma is completed with "rosebud" 3-0 delayed-absorbable stitches, which incorporate the ileal mucosa, intervening bowel serosa, and skin dermis (Fig. 43-6.7). Circumferential sutures are placed. To enable correct identification postoperatively, the right ureteral stent is cut at a right angle.

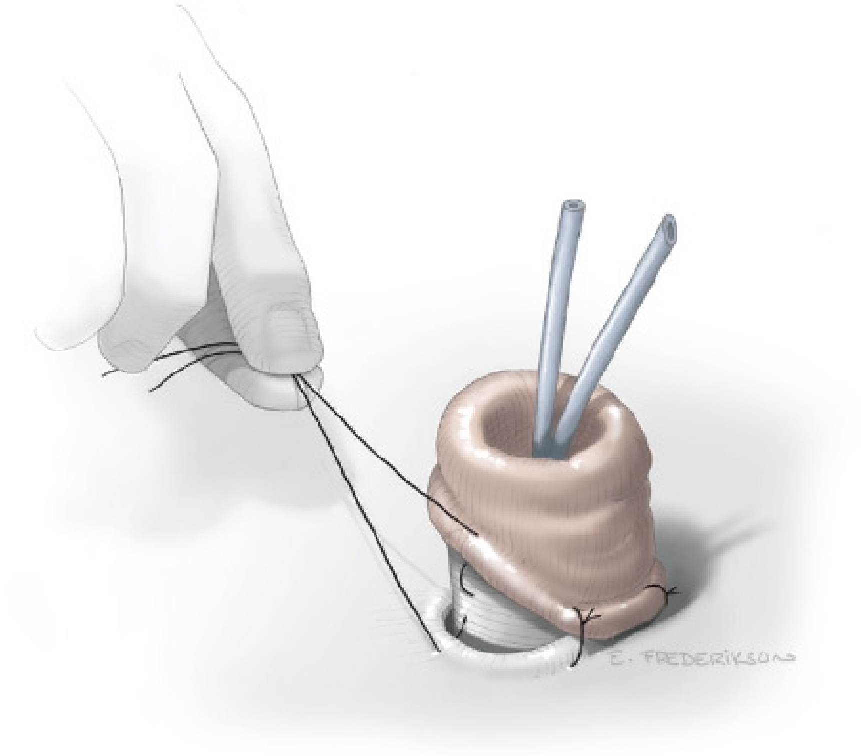
FIGURE 43-6.7



Source: Schorge JO, Schaffer JI, Halvorson LM, Hoffman BL, Bradshaw KD, Cunningham FG: *Williams Gynecology*: http://www.accessmedicine.com

Ileal conduit: suturing the stoma.

7. **Transverse Colon Conduit.** For this type of conduit, the hepatic and splenic flexures of the transverse colon generally must be mobilized. In addition, the right side of the omentum is detached. Division points are marked with Penrose drains and transected (Fig. 43-6.8). The mesocolon then is divided to the posterior abdominal wall.

   Intestinal continuity is re-established anterior to the conduit by a functional end-to-end anastomosis created using EEA and TA staplers. Ureters are sufficiently mobilized to reach the conduit. The ureteral anastomoses then are completed over stents (Beddoe, 1987). The stoma is made almost anywhere that the conduit will comfortably reach. The stomal end of the conduit is brought through the abdominal wall and secured (Fig. 43-6.9).

FIGURE 43-6.8

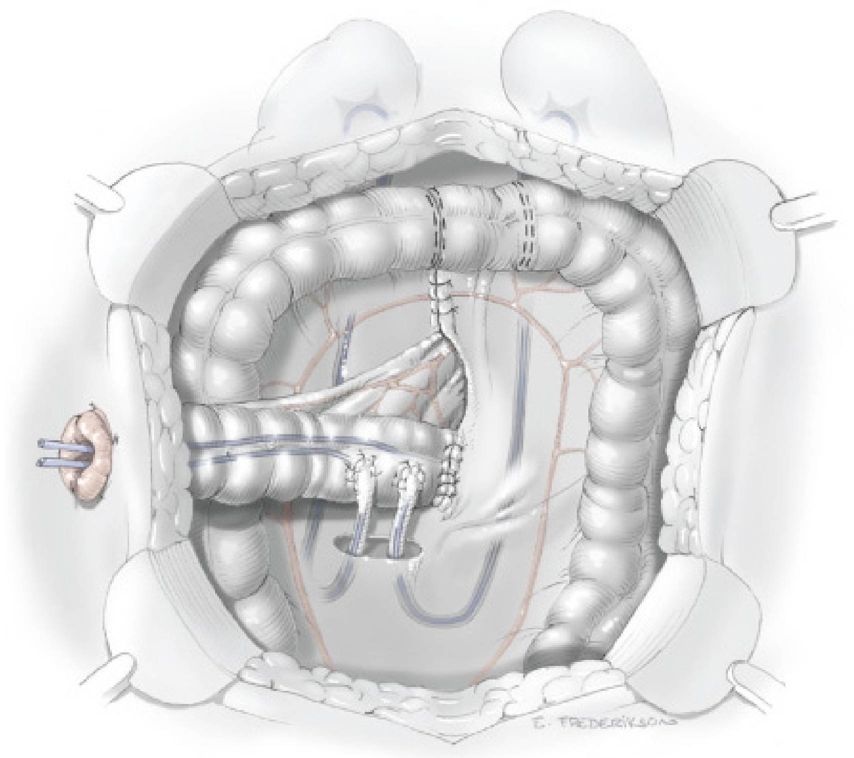
FIGURE 43-6.9



Source: Schorge JO, Schaffer JI, Halvorson LM, Hoffman BL, Bradshaw KD, Cunningham FG: *Williams Gynecology*: http://www.accessmedicine.com

Transverse colon conduit: final appearance.

8. **Final Steps.** To prevent postoperative sliding and ultimate tension on the anastomoses, the conduit's proximal end is secured to the posterior peritoneum with interrupted delayed-absorbable suture. Mesenteric defects require closure to prevent internal hernias, but not so tightly as to compromise blood supply. A suction drain may be placed if there is concern about the integrity of the anastomoses. The ureteral stent tips are cut to fit into the stoma appliance in a manner to differentiation which stent is on the right (cut at a right angle) and which is on the left (cut off straight). If the stoma appears dusky, the abdominal wall tunnel may be too tight, the mesentery may be twisted or placed on too much tension, or the blood supply may not be sufficient. The worst circumstance is the latter, and this generally requires the entire conduit to be redoneâ€”but may prevent catastrophic later complications.

Postoperative

The stoma should be checked regularly for viability during the immediate postoperative recovery period. Both stents should be functioning. A dry stent that does not respond to irrigation should prompt an imaging study to exclude obstruction. Urinary fistulas and obstructions are uncommon, but they are potentially life-threatening if they are not addressed with percutaneous drainage or re- operation (Bladou, 1995; Lichtinger, 1986). Prolonged bowel dysfunction may indicate an anastomotic urine leak or small bowel obstruction.

Patients often are re-admitted within a few weeks of surgery due to partial small bowel obstruction, urinary infection, wound separation, or other complications of exenteration. These typically resolve with targeted supportive care. Long-term complications include ureteral stenosis and renal loss. Renal function may deteriorate because of infection and reflux. Some patients may require stoma revision secondary to postoperative sloughing or retraction (Hancock, 1986).

Predictably, the overall morbidity of creating an incontinent conduit is much higher in previously irradiated patients (Houvenaeghel,

2004). Tissue quality and mobility are especially important in these patients.

43-7 CONTINENT URINARY CONDUIT

Removal of the bladder during total or anterior exenteration is the main indication for a continent urinary conduit. Vesicovaginal fistulas and disabling incontinence following radiation therapy are other, less common reasons (Lentz, 1995). Following cystectomy, urine is diverted into a reservoir created from a resected bowel segment. Depending on their construction, these diversions may render a woman continent or incontinent. An incontinent conduit reservoir chronically drains into an ostomy bag, whereas a continent conduit does not leak urine. Patients empty the reservoir by intermittent self-catheterization.

Continent conduits, however, may not be appropriate for all patients. The operation is more complex than an incontinent diversion procedure and may lead to more postoperative complications (Karsenty, 2005). They also require a highly motivated patient who is capable of long-term self-catheterization. An ideal candidate for a continent conduit is a young, otherwise healthy woman without a colostomy.

There are several continent diversion methods, and in gynecologic oncology, the continent ileocolonic urinary reservoir (Miami pouch) has become the most popular choice (Salom, 2004). This pouch is technically straightforward to construct and uses tissues that characteristically lie in nonirradiated areas (Penalver, 1998).

A Miami pouch includes a distal ileum segment, the ascending colon, and a portion of transverse colon. The basic steps involve opening the colon segment along the length of the tenia and folding it onto itself. The walls of the ascending and transverse colon are then sewn together to achieve a reservoir with low intraluminal pressure. The ileum segment is tapered, and purse-string sutures are placed at the level of the ileocecal valve to achieve continence. The ileal segment then is exteriorized as a stoma to allow catheterization (Penalver, 1989).

Preoperative

PATIENT EVALUATION

Preoperative evaluation usually is dictated by the preceding exenterative procedure. The specific decision is whether to plan for an incontinent or continent urinary conduit. Patients should be counseled extensively about the differences. The presence of a permanent colostomy removes the apparent advantage of a continent conduit and an abdominal wall without stomas. Moreover, catheterization may be more problematic in very obese women. Some patients with prior high-dose radiation or chronic bowel disease also may not be good candidates.

CONSENT

Patients should be advised that intraoperative findings such as poor bowel appearance and dense adhesions may dictate a change in original surgical plans. In addition, complications are common and should be reviewed. In experienced centers, half of patients will have one or more early pouch-related complications: ureteral stricture with obstruction, anastomotic leak, fistula, difficulty in catheterization, pyelonephritis, or sepsis. One third will develop late complications beyond 6 weeks. Ten percent of patients ultimately will require re-operation to revise the Miami pouch (Penalver, 1998).

PATIENT PREPARATION

Bowel preparation obviously is mandatory, but preparation generally is dictated by the preceding exenterative surgery. Ideally, an enterostomal therapist is available to mark a conduit stoma site. The site should be unobstructed in the supine, sitting, and standing positions.

Intraoperative

Surgical Steps

1. **Initial Steps.** The continent urinary conduit is constructed as the last major intra-abdominal procedure during exenterative surgery to avoid unnecessary traction on anastomoses. Before beginning the conduit, hemostasis should be achieved. Anesthesia requirements, patient positioning, and skin incisions typically are dictated by the preceding operation.

2. **Exploration.** The bowel segment should be inspected carefully at the planned conduit site. It must be healthy appearing without severe radiation injury. At this point, the final decision to proceed with creation of a Miami pouch is made.

3. **Preparing the Bowel Segment.** The right colon is freed from the cecum around the hepatic flexure to the proximal transverse colon along the white line of Toldt. This line is the reflection of posterior abdominal parietal peritoneum over the mesentery of the descending colon. The conduit will require about 25 to 30 cm of colon and at least 10 cm of ileum. With these measurements in mind, a surgeon selects sites to divide the bowel (Fig. 43-7.1).

   The mesentery is scored with an electrosurgical blade, and a Penrose drain is placed around the sections to be divided. Within the mesentery, the underlying vasculature is reviewed to ensure sufficient conduit blood supply. A GIA stapler is used to divide the bowel at both sites marked with the Penrose drains (see Fig. 43-7.1).

   The mesenteries are incised down through the avascular areas to the posterior peritoneum. At this point, intestinal continuity is re-established by a functional end-to-end stapled ileotransverse enterocolostomy using the GIA and TA staplers. The mesenteric defect is closed with delayed-absorbable suture in a running fashion.

FIGURE 43-7.1

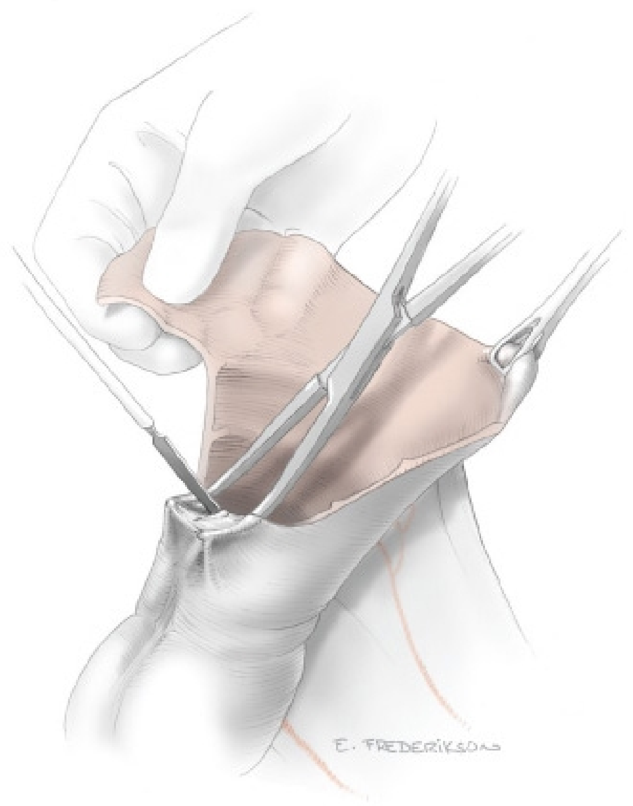
Preparing the bowel segment.

4. **Detubularizing the Bowel.** The conduit staple lines are removed with Metzenbaum scissors, and the bowel is irrigated into a basin. Of this bowel segment, the entire colon portion is opened with an electrosurgical blade along the tenia of the

antimesenteric border to "detubularize" the bowel and remove the appendix (Fig. 43-7.2).

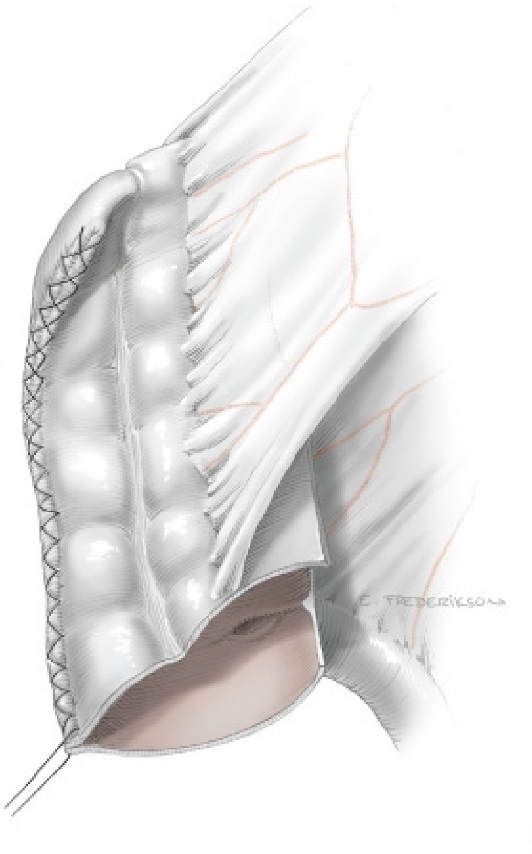
FIGURE 43-7.2



Detubularizing the bowel.

5. **Creating the Pouch.** The colon segment is folded in half, and four delayed-absorbable stay sutures are placed at the corners to begin creation of the pouch. One lateral edge is closed in two layers with 2-0 and 3-0 delayed-absorbable suture in a running fashion (Fig. 43-7.3).

FIGURE 43-7.3

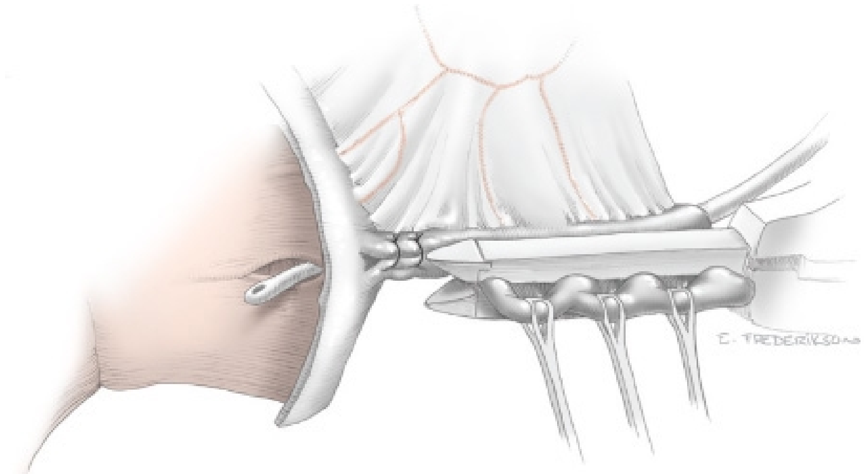


Source: Schorge JO, Schaffer JI, Halvorson LM, Hoffman BL, Bradshaw KD, Cunningham FG: *Williams Gynecology*: http://www.accessmedicine.com

Creating the reservoir.

6. **Tapering the Ileum.** A 14F red rubber catheter is inserted through the terminal ileum segment into the pouch. Two purse-string delayed-absorbable sutures are placed 1 cm apart at the ileocecal junction. The ileum is elevated with Babcock clamps, and a GIA stapler is used to taper the terminal ileum on its antimesenteric border over the catheter (Fig. 43-7.4). An abdominal wall opening is made in the right lower quadrant so that the ileal segment of the conduit can be pulled through to approximate its final position (see Figs. 43-6.5 and 43-6.6).

FIGURE 43-7.4



Source: Schorge JO, Schaffer JI, Halvorson LM, Hoffman BL, Bradshaw KD, Cunningham FG: *Williams Gynecology*: http://www.accessmedicine.com

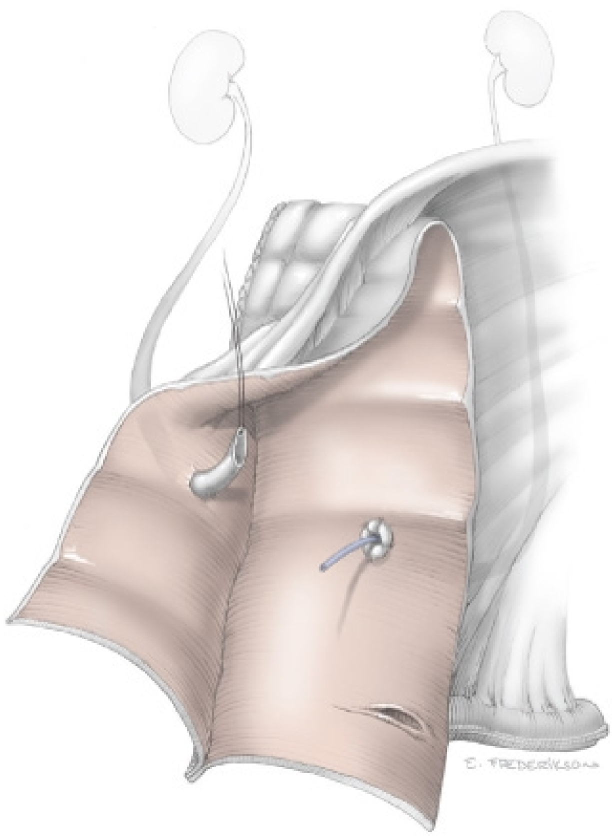
Tapering the ileum.

7. **Ureteral Anastomoses.** Both ureters are further mobilized from their retroperitoneal attachments and brought into position under the ascending mesocolon. To avoid crush injury and subsequent necrosis, they never should be grasped or handled roughly. Their anastomotic sites to the pouch are selected based on ureter length and their ability to have a straight course to the pouch.

   One ureter usually is brought through on either side of the posterior pouch suture line. The ureters are trimmed and spatulated (see Fig. 43-6.3). The bowel mucosa is incised away from the suture line (see Fig. 43-6.2). A hemostat is poked through the bowel wall to bring 2 cm of each ureter into the pouch by pulling on the traction suture (Fig. 43-7.5).

   Each ureter is secured to the bowel mucosa with interrupted stitches of 4-0 delayed-absorbable suture. Ureteral stents (6F or 7F) are inserted and sutured to the bowel wall with 3-0 plain catgut to stabilize their placement.

FIGURE 43-7.5



Source: Schorge JO, Schaffer JI, Halvorson LM, Hoffman BL, Bradshaw KD, Cunningham FG: *Williams Gynecology*: http://www.accessmedicine.com

Ureteral anastomoses.

8. **Closing the Pouch.** A large Malecot catheter is brought into the pouch away from the ileocecal valve. The ureteral stents are brought out through the pouch next to the Malecot (Fig. 43-7.6). A watertight purse-string 3-0 plain catgut suture is placed where the catheters exit the pouch. The remaining lateral edges of the pouch are sutured closed with two layers of 2-0 and 3-0 delayed-absorbable suture in a running fashion. Continence may be tested by filling the pouch with 250 to 300 mL of saline and removing the red rubber catheter (Fig. 43-7.7). Additional purse-string sutures may be placed at the ileocecal valve if incontinence is demonstrated.

FIGURE 43-7.6

Final steps.

9. **Final Steps.** The ileal segment is pulled through the abdominal wall and may require trimming to sit flush. The stoma is created by placing interrupted stitches of 3-0 delayed-absorbable suture between the dermis and ileal mucosa. A red rubber catheter should be inserted and withdrawn to make sure that the pouch can be accessed easily. A Jackson-Pratt (JP) drain then is placed near the pouch and brought out through a separate stab wound away from the stoma.

   The two stents and Malecot drain are brought out through a separate stab wound away from the stoma site and individually fixed to the skin with nylon sutures. These will be removed later postoperatively.

Postoperative

The Miami pouch initially requires more care than an incontinent urinary conduit. Mucus will be produced by the colonic bowel segment. Therefore, the Malecot catheter should be irrigated every few hours to permit urine drainage. In contrast, the ureteral stents are irrigated only if one of the catheters becomes obstructed. Two to 3 weeks postoperatively, an intravenous pyelogram (IVP) and gravity pouchogram should be performed. If these tests are normal, the ureteral stents, Malecot catheter, and JP suction drainage tube all may be removed.

The patient may be taught self-catheterization using an 18F to 22F red rubber catheter and antiseptic technique. Catheterizations may be progressively spaced over weeks to finally be required only every 6 hours during the day and not at night. In addition, the pouch requires periodic irrigation to remove mucus. An IVP, pouchogram, and serum electrolytes and creatinine determinations are performed at 3 months postoperatively and then every 6 months to evaluate the pouch, renal function, and upper urinary tracts.

More than half of patients will have a conduit-related complication postoperatively. Fortunately, most may be managed successfully conservatively without the need for re-operation (Ramirez, 2002). The most common urinary complications are ureteral stricture or obstruction, difficult catheterization, and pyelonephritis (Angioli, 1998; Goldberg, 2006). The gastrointestinal complication rate attributed to the Miami pouch is less than 10 percent and includes fistulas (Mirhashemi, 2004).

43-8 VAGINAL RECONSTRUCTION

Patients undergoing exenterative surgery are typical candidates for creation of a new vagina. Other less common indications include congenital absence of the vagina, postirradiation stenosis, and total vaginectomy. There are innumerable ways to perform the procedure, and the type of reconstruction typically is determined by both the surgeon's personal experience and the woman's clinical circumstances.

Vaginal reconstruction at the time of exenteration is a very personal choice. Not every woman will desire a new vagina, and others will be unhappy with the functional result (Gleeson, 1994a). Reconstruction significantly prolongs an already lengthy operation and may lead to additional perioperative morbidity (Mirhashemi, 2002). However, proponents suggest that filling the large pelvic defect and bringing in a new source of blood supply may prevent postoperative fistula or abscess formation (Cain, 1989; Jurado, 2000).

Of the reconstruction choices, *pudendal thigh fasciocutaneous flaps* are technically easy to perform, but rates of sexual satisfaction are disappointingly low (Gleeson, 1994b). An omental flap with *split-thickness skin graft* (STSG) is another straightforward procedure with minimal morbidity (Kusiak, 1996). *Rectus abdominis myocutaneous* (RAM) *flaps* and *gracilis myocutaneous flaps* (GMC) are technically more challenging, take longer to perform, but demonstrate the most satisfying functional results (Lacey, 1988; Smith, 1998). Regardless of reconstruction technique, sexual adjustment is often significantly impaired in women after pelvic exenteration (Ratliff, 1996). Other techniques are used less commonly and will not be covered in this section.

Preoperative

PATIENT EVALUATION

The surgeon should have an open discussion with the patient about the risks and benefits of vaginal reconstruction. Some women may have unrealistic expectations that are important to address preoperatively. Others may not wish to incur additional morbidity. The patient also should be aware that intraoperative complications may dictate a change of plans and the need to abort reconstruction.

CONSENT

Patients who are motivated to undergo creation of a new vagina must be counseled very carefully. Postoperative patient concerns are expected and include self-consciousness about being seen in the nude by their partner, vaginal dryness, and vaginal discharge (Ratliff, 1996). The potential morbidity of the neovagina depends on the type of reconstruction. Flap necrosis, prolapse, wound separation, or other complications may require re-operation or lead to an unsatisfying end result or both.

PATIENT PREPARATION

The preceding exenterative surgery typically dictates preoperative preparation. Modifications may be required depending on the type of neovaginal reconstruction. For example, the legs may need to be surgically prepared beyond the knees (gracilis flap), or a suitable donor site may need to be identified (STSG).

Intraoperative

Surgical Steps

1. **Pudendal Thigh Fasciocutaneous Flap.** From a perineal approach, the planned incisions are marked along the skin from the non-hair-bearing areas just lateral to the labia majora. Flaps should be roughly 15 × 6 cm. The most inferior skin margin should be level with the lower part of the gaping perineal defect. The skin incision is begun at the superior flap margin and dissected to include the underlying subcutaneous tissue and fascia lata (Fig. 48-8.1). The posterior labial artery, which is a branch of the internal pudendal artery, provides blood supply.

   The flap's edges are approximated in a running subcuticular suture line with 4-0 delayed-absorbable suture. The neovagina is

inserted into the perineal defect, and the incision sites are closed with interrupted stitches of 3-0 delayed-absorbable suture. Bilateral Jackson-Pratt (JP) drains have been placed beneath the harvest sites to prevent seroma formation. The perineal defect also generally requires some suturing for closure (Fig. 48-8.2). The apex of the neovagina then may be sutured abdominally to the hollow of the sacrum and covered with an omental J-flap to provide additional neovascularization.

Perineal flap closure.

2. **Omental J-Flap with Split-Thickness Skin Graft.** Modification of the omental flap, which normally is used to close off the pelvic inlet after exenteration, can create a cylinder providing anterior, posterior, and lateral walls for a new vagina.

   From an abdominal approach, the omentum is detached from the stomach with a ligate-divide-staple (LDS) device, usually from right to left, until it will comfortably reach the pelvis as a J-flap (see Section 43-12, Omentectomy). Only three quarters of the omentum is divided to preserve the left gastroepiploic artery. The distal omentum is rolled into a cylinder and sutured together with interrupted stitches of 3-0 gauge delayed-absorbable suture (Fig. 43-8.3). The proximal end can be closed with interrupted sutures or a TA stapler. The omental cylinder then is sutured to the vaginal introitus.

   The STSG is harvested from the donor site and sutured over a vaginal mold with 4-0 delayed-absorbable suture (see Fig. 41-12.1). From a perineal approach, the mold is placed into the neovaginal space and sutured into place at the introitus (Fig. 43-8.4). The STSG skin harvest sites are covered with a Tegoderm dressing.

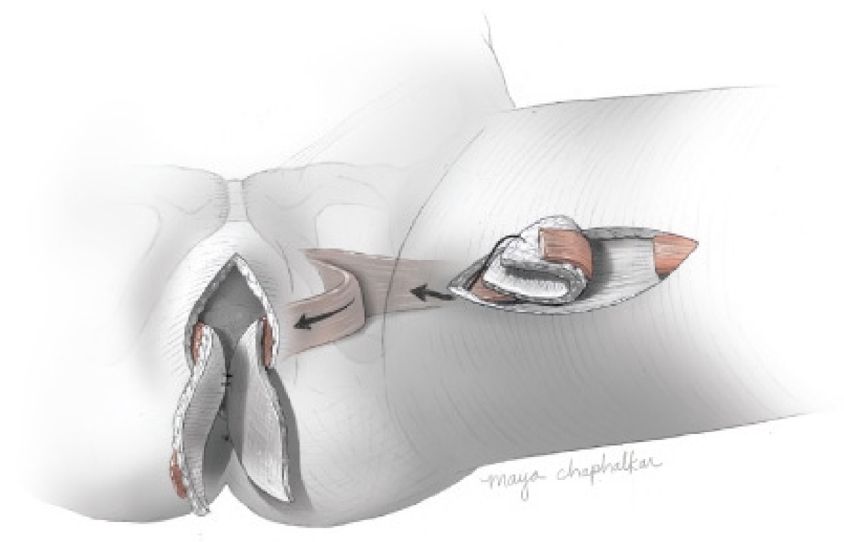
Insertion of the split-thickness skin graft (STSG).

3. **Gracilis Myocutaneous Flap.** From a perineal approach, a reference line is drawn on the medial thigh from the pubic tubercle to the medial tibial plateau. This line follows the adductor longus muscle. Posterior to this line, an island of skin, its associated subcutaneous tissue, and the gracilis muscle will serve as the flap (Fig. 43-8.5). The planned elliptic incision is marked, and a full-thickness skin incision through the reference line is continued through the subcutaneous fat and the fascia lata. The belly of the gracilis muscle is isolated at its distal margin and divided. The remainder of the incision is completed around the marked skin island margin. The gracilis is mobilized fully with blunt and sharp dissection from distal to proximal. This preserves the dominant vascular pedicleâ€”a branch of the medial femoral circumflex artery. This vessel enters the deep anterior belly of the muscle about 6 to 8 cm from the pubic tubercle.

   Through the operative site, a subfacial tunnel is bluntly developed medially to the open perineal defect. The left gracilis muscle flap is rotated clockwise against the thigh, i.e., rotated first posteriorly and then medially. It is placed through the tunnel and allowed to hang freely between the patient's legs. The right flap is rotated counterclockwise and similarly positioned.

   Beginning at the distal tip, the tubular gracilis neovagina is constructed by suturing the skin edges of the right and left skin islands together with interrupted stitches using 4-0 delayed-absorbable suture. The proximal opening should accommodate two or three fingers. The neovagina is rotated cephalad into the pelvis and anchored posteriorly to the levator plate abdominally. This suturing prevents prolapse. Redundant flap skin is trimmed, and the proximal skin is sutured to the introitus with interrupted stitches of 3-0 delayed-absorbable suture. The graft harvest incision sites are closed with interrupted stitches of 3-0 delayed-absorbable suture.

FIGURE 43-8.5



Source: Schorge JO, Schaffer JI, Halvorson LM, Hoffman BL, Bradshaw KD, Cunningham FG: *Williams Gynecology*: http://www.accessmedicine.com

Gracilis myocutaneous (GMC) flap.

4. **Rectus Abdominis Muscle Flap.** A skin island can be harvested from any location on the abdominal wall as long as its base is at the umbilicus. Typically, a 10 × 15 cm skin island is marked, and at its superior border, the skin, subcutaneous tissue, and anterior rectus sheath are incised. One belly of the rectus abdominis muscle is freed with blunt dissection from the posterior sheath (Fig. 43-8.6). The belly is divided proximally, and anastomotic vessels connecting to the superior epigastric system are ligated.

   The remaining borders of the skin island are incised through the anterior rectus sheath to the arcuate line, and the subcutaneous fat is mobilized along the lateral and medial margins of the rectus muscle belly. The rectus muscle then is dissected bluntly from the posterior sheath to raise the flap. The peritoneum is cut inferiorly, beginning at the arcuate line and extending the full length of the midline incision well beyond the flap. The rectus muscle then is dissected bluntly inferiorly from the anterior sheath to its insertion onto the pubic bone. The inferior rectus flap then can be rotated posteriorly into the pelvis.

   The flap is coiled around a syringe to form a tube (Fig. 43-8.6). The skin edges are approximated with 4-0 delayed-absorbable suture. The syringe is removed, and the tube is placed into the pelvis. The pelvic end is closed. The RAM flap must be put into the pelvis without tension to prevent occlusion of the dominant vascular supply from the inferior epigastric artery.

   The open end of the neovagina is brought out under the pubic symphysis to the perineum, where it is attached to the vulvar defect using interrupted vertical mattress stitches using delayed-absorbable suture. An omental J-flap also may be prepared to provide additional blood supply.

   Typically the abdominal wall defect can be closed primarily. The ipsilateral adjacent skin should first be undermined. Next, the operating table can be partially flexed to reduce tension on the closure. The posterior sheath is brought toward the midline and closed by running a monofilament permanent suture. The anterior rectus sheath does not necessarily require separate closure, but if desired, a defect can be covered with mesh placement. After closing the fascia, a JP suction drain is inserted in the wound site before completing the skin closure with staples.

Rectus abdominis myocutaneous (RAM) flap.

Postoperative

The presence of a vagina significantly improves a woman's quality of life and reduces sexual problems after exenteration (Hawighorst-Knapstein, 1997). Vaginal reconstruction may be beneficial to a patient's self-image. The knowledge that intercourse is possible may be reassuring even if she chooses not to be sexually active postoperatively. Morbidity from the procedure largely depends on the type of neovagina.

Pudendal thigh flaps are the easiest to perform but perhaps also the most likely to be nonfunctional. Long-term sequelae may include vulvar pain, chronic vaginal discharge, hair growth, and protrusion of the flaps. These symptoms may discourage patients and their partners from attempting sexual activity (Gleeson, 1994b).

Omental flap/STSG neovaginas may become infected at the donor or recipient site. Sloughing is a common complication, especially in previously irradiated patients. In addition, stenosis may develop unless dilators are used postoperatively or sexual intercourse is regular.

Gracilis myocutaneous flaps may be difficult to pass into the pelvis during the procedure and have the potential for partial or complete tissue loss owing to necrosis from an inherently tenuous blood supply (Cain, 1989). Flap loss is significantly more common with rectosigmoid anastomosis during exenteration (Soper, 1995). Long term, prolapse is another relatively common problem. Residual scarring on the legs is a common, albeit relatively minor, complaint postoperatively.

Rectus abdominis muscle flaps are perhaps the best choice for vaginal reconstruction at the time of pelvic exenteration. Ideally, they fill pelvic dead space, reduce the risk of fistulas, and provide fulfilling sexual activity (Goldberg, 2006). However, the donor site may be difficult to close primarily or lead to a postoperative hernia or dehiscence. The operating time is also increased because two surgical teams are not possible. Flap necrosis, fistula, and vaginal stricture or stenosis are other frequent complications (Soper, 2005).

43-9 PELVIC LYMPHADENECTOMY

Pelvic lymph node removal of is one of the hallmarks of surgical staging and is commonly indicated for patients with uterine, ovarian, and cervical cancer. Pelvic lymphadenectomy implies a complete removal of all nodal tissue within an area bordered by well-defined anatomic landmarks. These include: midportion of the common iliac artery (proximally), circumflex iliac vein (distally), midportion of the psoas muscle (laterally), ureter (medially), and obturator nerve (posteriorly) (Whitney, 2005).

Additional definitions are used commonly in association with lymphadenectomy. For example, pelvic lymph node *sampling* is a more limited procedure within the same anatomic boundaries and is particularly intended to remove any enlarged or suspicious nodes (Whitney, 2005). Sampling has some valid indications depending on the clinical circumstances but is not a reliable method for accurately excluding nodal metastases (Carnino, 1997). Pelvic lymph node *dissection* is a vague term that may range from sampling to lymphadenectomy.

Removal of at least four lymph nodes from each side (right and left) is a minimum requirement to validate that an adequate lymphadenectomy has been performed (Whitney, 2005). Ideally, the procedure should yield more than 11 pelvic nodes from multiple sites (Cragun, 2005). However, removal of more lymph nodes increases the risk of postoperative complications (Franchi, 2001). In general, the extent of pelvic lymphadenectomy will depend on the clinical circumstances and will vary by clinician. Moreover, lymphadenectomy completeness is not only a reflection of total node counts but also depends on diagnostic skills of the interpreting pathologist.

Removal of enlarged pelvic nodes may be required to achieve optimal debulking of ovarian cancer. In addition, debulking of grossly involved pelvic lymph nodes also may confer a survival benefit in selected endometrial and cervical cancer patients (Havrilesky, 2005; Kupets, 2002). However, there is controversy as to whether systematic removal of pelvic nodes confers a true survival benefit or solely provides more accurate staging information in otherwise "understaged" patients (Panici, 2005).

Pelvic lymphadenectomy usually is an open procedure. The emerging laparoscopic approach has a learning curve to achieve adequate nodal counts (Kohler, 2004; Schlaerth, 2002). Extraperitoneal pelvic lymphadenectomy is performed even less commonly (Larciprete, 2006). Preoperative identification of suspicious nodes by lymphatic mapping and sentinel node identification remains an experimental strategy in gynecologic cancer surgical staging (Di Stefano, 2005; Levenback, 2002).

Preoperative

PATIENT EVALUATION

Imaging studies such as computed tomographic (CT) scanning and magnetic resonance (MR) imaging are commonly performed preoperatively in women undergoing cancer-related surgery. These studies may suggest the presence of pelvic lymphadenopathy and help to guide a surgeon to the most suspicious areas.

CONSENT

Pelvic lymphadenectomy should be a straightforward procedure with few complications, but acute hemorrhage, postoperative lymphocyst, and obturator nerve injury are possible (Bosze, 1993). Obesity, previous radiation, prior pelvic infections, prior abdominal surgery, and other factors causing retroperitoneal fibrosis can add difficulty to dissection. Most of these destroy tissue planes and can lead to an increased risk of complications.

PATIENT PREPARATION

Routine bowel preparation and antibiotic prophylaxis are not required for lymphadenectomy but may be indicated for other concurrent surgeries.

Intraoperative

Surgical Steps

1. **Anesthesia and Patient Positioning.** Lymphadenectomy may be performed under general or regional anesthesia with a patient in supine position. A Foley catheter is placed, and the abdomen is surgically prepared.

2. **Abdominal Entry.** A midline vertical or transverse abdominal incision that allows adequate visualization is appropriate for this procedure. Self-retaining retractors should be adjusted to expose the external iliac artery in its entirety.

3. **Abdominal Exploration.** Pelvic lymph nodes should be palpated routinely during initial abdominal exploration. Unexpected grossly positive nodes may indicate that a proposed operative plan should be revised or abandoned (e.g., radical hysterectomy for cervical cancer) (Whitney, 2000).

4. **Retroperitoneal Exploration.** The retroperitoneal space typically already has been entered through the round ligament during preceding surgical procedures. However, to improve visibility, a surgeon may further extend anterior and posterior broad ligament leaf openings.

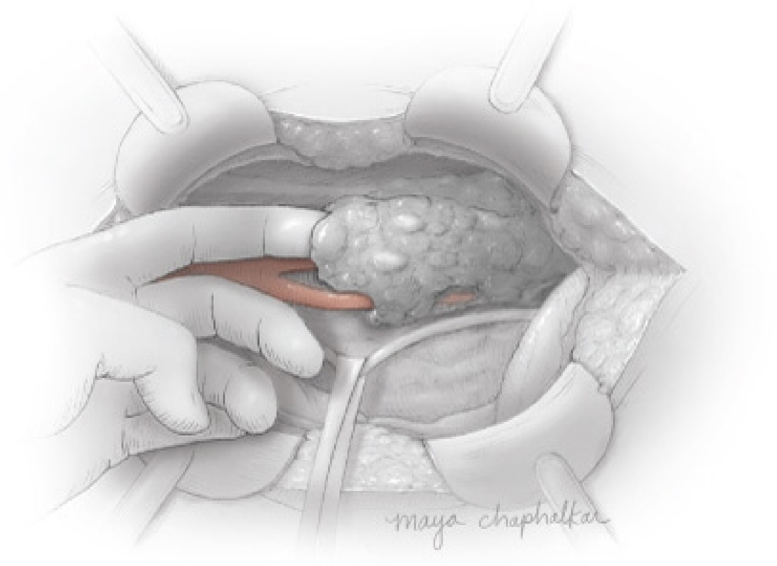
   Palpation of the external iliac artery pulsation just medial to the psoas major muscle should be the starting point, and its identification permits surgeons to locate relevant anatomy. Blunt dissection then is performed to visualize the bifurcation of the external and internal iliac arteries. The ureter is isolated, as described previously (see Section 43-1, Radical Abdominal Hysterectomy (Type III), Step 5). The remaining pelvic sidewall structures are covered with fatty lymphoid tissue and are not yet easily visible.

5. **Lateral Dissection.** An index finger is placed lateral to the bifurcation and used to bluntly dissect parallel to the external iliac artery along the psoas major muscle (Fig. 43-9.1). The general lack of arterial and venous branches along the external iliac vessels enables aggressive blunt dissection to be performed unless there is significant fibrosis. This maneuver separates the lateral preperitoneal fat from the medial fatty lymphoid tissue covering the vessels.

   Nodal tissue next is reflected medially to reveal the entire external iliac artery. Forceps traction and electrosurgical cutting typically are required to lift all adventitial tissue above the artery and maintain the correct plane of dissection. The circumflex iliac vein should be visible crossing over the distal external iliac artery before proceeding (see Fig. 43-9.3). The genitofemoral nerve should be visible parallel to the artery and overlying the psoas muscle.

   Bleeding is a common problem with pelvic lymphadenectomy that may be exacerbated by retroperitoneal fibrosis. Usually venous bleeding or avulsion of small vessel branches can be controlled quickly with vascular clips. Vascular anomalies are encountered regularly and may cause inadvertent hemorrhage if not identified.

FIGURE 43-9.1



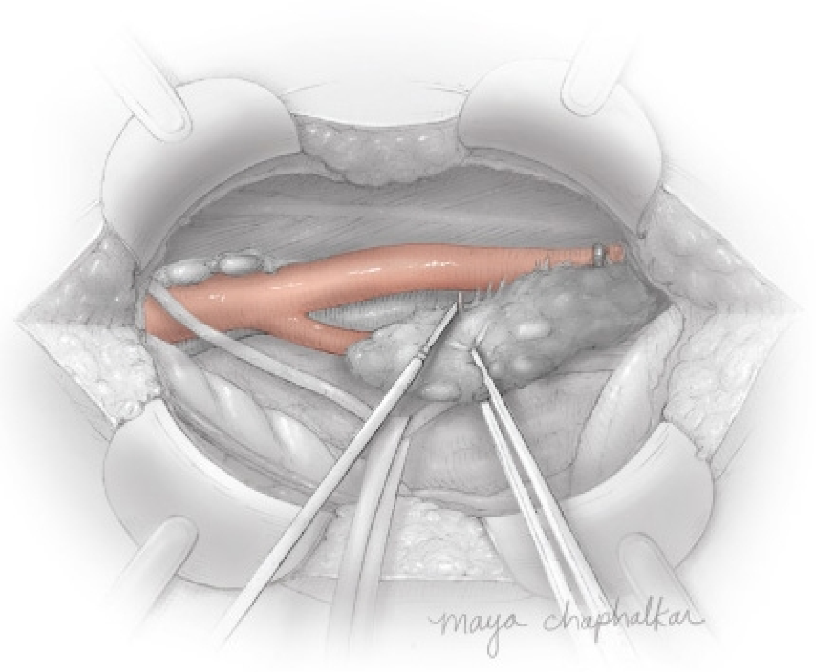
Source: Schorge JO, Schaffer JI, Halvorson LM, Hoffman BL, Bradshaw KD, Cunningham FG: *Williams Gynecology*: http://www.accessmedicine.com

Mobilizing the lateral nodal tissue.

6. **Removal of Distal Nodes.** A distal self-retaining retractor blade may need to be removed temporarily to resect all pelvic nodes heading toward the inguinal canal. The distal round ligament tie is elevated with one hand. The thumb of the other hand should be advanced directly beneath the round ligament and followed to the inguinal ring. Apposition of the tip of the thumb with the middle and adjoining fingertips will enable palpation, distal pinching, and removal of nodal tissue without cutting, clamping, or meaningful blood loss. The retractor blade then may be replaced.

7. **Dissection over the External Iliac Vein.** The ureter should be held medially on tension by Penrose drain to promote visualization of the pelvic sidewall. Forceps are used to place the nodal tissue bundle on medial traction. Alternating electrosurgical and blunt dissections are performed to reflect the nodal tissue medially until the external iliac vein is visualized (Fig. 43-9.2). The dissection is continued from proximal to distal above the internal iliac vessels. Nodal tissue may be transected with blunt and electrosurgical blade dissection along the inferomedial wall of the external iliac vein. The distal end of the bundle usually is tethered to the sidewall. Nodal tissue may be removed by placing a vascular clip and dividing the attachment. Additional fatty lymphoid tissue typically is seen within the anatomic boundaries. These nodes may be more adhered to the vessel and can be removed separately and added to the specimen.

FIGURE 43-9.2



Source: Schorge JO, Schaffer JI, Halvorson LM, Hoffman BL, Bradshaw KD, Cunningham FG: *Williams Gynecology*: http://www.accessmedicine.com

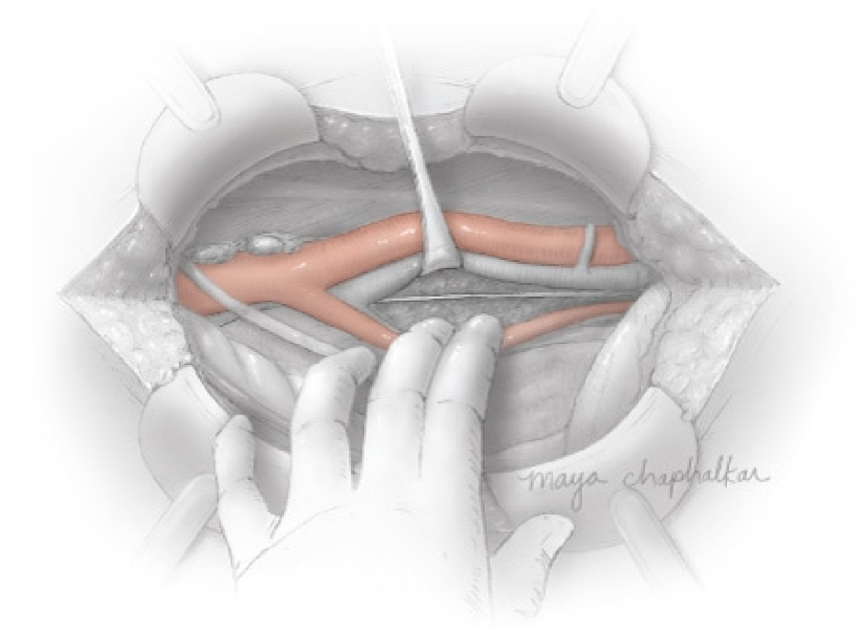
Medial dissection over the vein.

8. **Obturator Fossa Nodes.** The index finger is gently inserted between the psoas major muscle and the external iliac artery. Blunt dissection progresses downward to the obturator fossa. Lateral arterial or venous branches may need to be clipped and cut. Nodal tissue may be identified behind the external iliac vessels and added to the specimen.

   A vein retractor then is used to elevate the external iliac vein and expose the obturator fossa (Fig. 43-9.3). Debakey forcep tips can be used to mobilize nodal tissue inferiorly from the bottom of the vein. Accessory venous branches may be identified and clipped. The vein retractor then is removed and a hand inserted with the thumb directly beneath the vein. The tip of the thumb is advanced laterally, and the nodal bundle is scooped over the fingertips. This nodal packet may be removed by gently pinching along the pelvic sidewall.

   The obturator nerve may be palpable, and dissection purposely should remain superior. Firm fibrotic attachments may be dissected electrosurgically under direct visualization. The vein retractor is then reinserted, and the obturator nerve should be visible. Additional areas of fatty lymphoid tissue can be seen. Further blunt dissection is continued until the entire portion of the obturator fossa that lies anterior to the nerve is empty. Nodal tissue below the obturator nerve is not removed routinely because the obturator artery and vein traverse this area. Laceration of either of these vessels can result in retraction and catastrophic hemorrhage that is difficult to control.

FIGURE 43-9.3



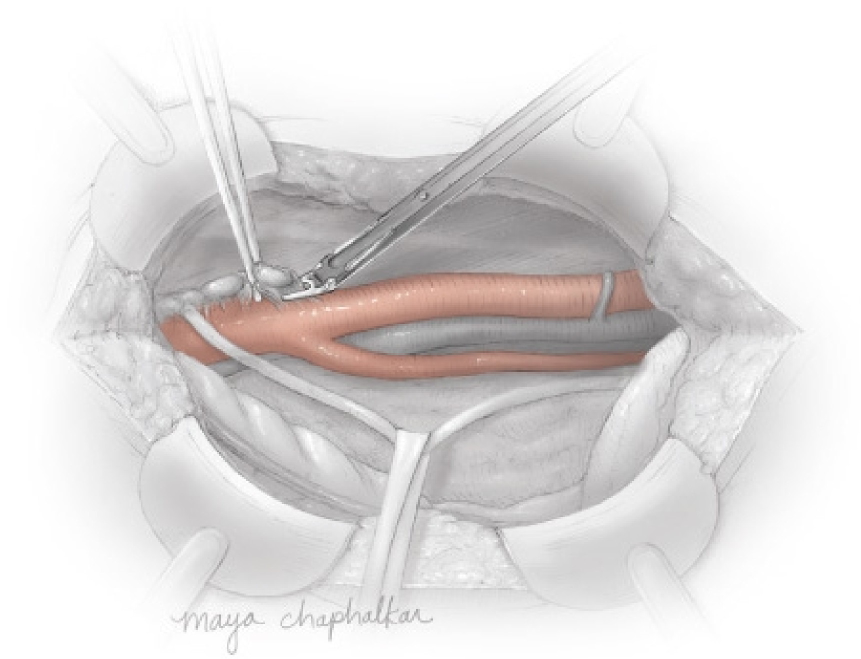
Source: Schorge JO, Schaffer JI, Halvorson LM, Hoffman BL, Bradshaw KD, Cunningham FG: *Williams Gynecology*: http://www.accessmedicine.com

Obturator fossa dissection.

9. **Distal Common Iliac Lymph Node Dissection.** The upper retractor blade is re-adjusted to allow increased visibility of the distal half of the common iliac artery. The colon may require mobilization using electrosurgical dissection along the white line of Toldt. Bowel then can be retracted sufficiently to allow access to the common iliac nodes.

   The lateral fatty lymphoid tissue may be removed by first grasping it with Debakey forceps and using electrosurgical dissection to establish a plane. Blunt dissection then may be performed in a proximal direction to further separate the nodal tissue from the artery. Electrosurgical coagulation or clips then may be used to detach the nodes (Fig. 43-9.4). Caution should be used on the right side because of the proximity of the underlying external iliac and common iliac veins and inferior vena cava (IVC). During lymphadenectomy, small veins that enter the anterior surface of IVC may be avulsed.

FIGURE 43-9.4



Source: Schorge JO, Schaffer JI, Halvorson LM, Hoffman BL, Bradshaw KD, Cunningham FG: *Williams Gynecology*: http://www.accessmedicine.com

Distal common iliac dissection.

10. **Final Steps.** Gauze sponges may be opened and tightly placed into the obturator fossa and medial to the external iliac vein to tamponade any surface oozing while additional procedures are performed. There is no benefit to closing the retroperitoneal space or routinely using pelvic suction drainage (Bafna, 2001; Lopes, 1995; Suzuki, 1998).

Postoperative

Surgical blunt dissection techniques decrease the risk of inadvertent vessel or nerve injury but may increase the chance of postoperative lymphocyst formation. Also known as *lymphocoele,* these cysts usually are asymptomatic, transient collections of lymph with a thick fibrotic wall. Symptomatic or large lymphocysts usually will respond to percutaneous aspiration with or without drainage catheter placement (Mann, 1989). Sclerosis is uncommonly required. Laparotomy with marsupialization should be considered a last option (Liu, 2005). Omentoplasty may reduce the incidence of these complications but is not usually performed (Fujiwara, 2003).

Contusion is the most common type of obturator nerve injury. This functional complication may be indicated by motor or sensory changes as described in Chapter 40, Obturator Nerve Injury and typically resolves with time. However, transection of the obturator nerve should be immediately noted intraoperatively and an epineural repair performed (Vasilev, 1994).

43-10 PARA-AORTIC LYMPHADENECTOMY

Para-aortic lymphadenectomy implies a complete removal of all nodal tissue from within an area with well-defined anatomic boundaries. These include the inferior mesenteric artery (proximally), middle common iliac artery (distally), ureter (laterally), and aorta (medial) (see Fig. 38-15). The completeness of the procedure will vary by clinician, but an adequate dissection requires that lymphatic tissue at least be demonstrated pathologically from both the right and left sides (Whitney, 2005).

Removal of para-aortic lymph nodes is indicated routinely to surgically stage women with uterine and ovarian cancer because of their unpredictable patterns of lymphatic dissemination (Burke, 1996; Negishi, 2004). Moreover, removal of enlarged para-aortic nodes may be required to achieve optimal debulking of ovarian cancer and also may confer a survival benefit in selected endometrial and cervical cancer patients (Cosin, 1998; Havrilesky, 2005).

Para-aortic lymphadenectomy usually is an open procedure. Transperitoneal laparoscopic approach is available, although adequate nodal counts depend in large part on operator laparoscopic skills (Kohler, 2004).

Preoperative

PATIENT EVALUATION

Imaging studies such as computed tomographic (CT) scanning and magnetic resonance (MR) imaging may suggest the presence of para-aortic lymphadenopathy but are not completely accurate. For example, occult macroscopically positive para-aortic nodes are encountered commonly during ovarian cancer debulking (Eisenkop, 2001). Preoperative tests may help to guide a surgeon to the most suspicious areas but are not mandatory in most circumstances.

CONSENT

Para-aortic lymphadenectomy is not performed routinely worldwide because of the procedure's difficulty and potential for complications (Fujita, 2005). Of these, acute hemorrhage and postoperative ileus are associated most commonly. Other complications should be infrequent. However, in an obese woman, visibility in the area of dissection is decreased, and thus, the complexity of performing this delicate procedure is increased. The operative time is also lengthened considerably.

PATIENT PREPARATION

Routine bowel preparation and antibiotic prophylaxis typically are not required. However, other concurrent surgeries may dictate their use.

Intraoperative

Surgical Steps

1. **Anesthesia and Patient Positioning.** Lymphadenectomy may be performed under general or regional anesthesia with the patient in supine position. A Foley catheter is placed, and the abdomen is surgically prepared.

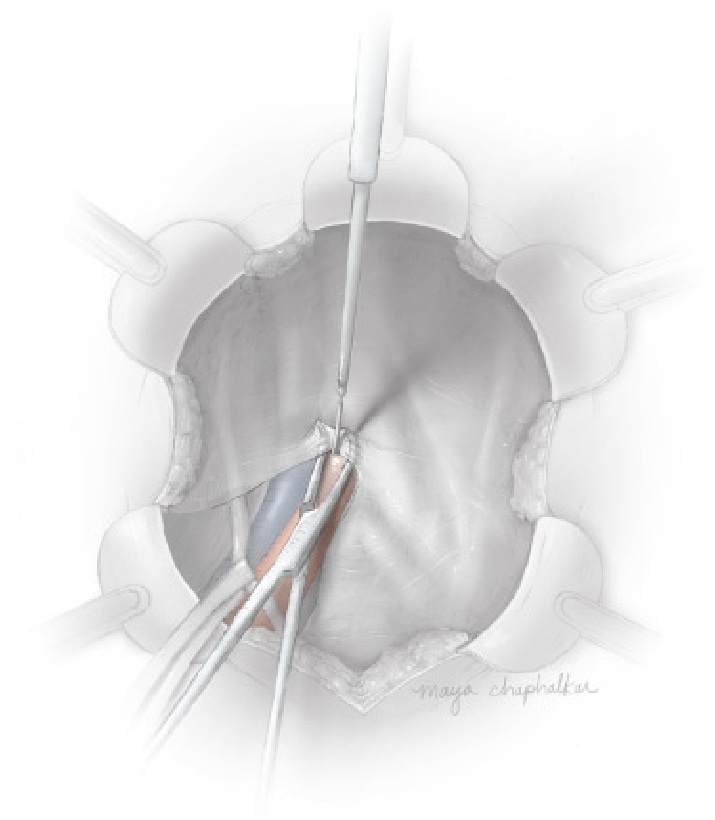
2. **Abdominal Entry.** A midline vertical abdominal incision that extends around and above the umbilicus provides optimal exposure. Alternatively, para-aortic lymphadenectomy also can be performed via a Cherney or a Maylard incision (see Sections 41-3, Cherney Incision and 41-4, Maylard Incision) (Helmkamp, 1990). A Pfannenstiel incision, in contrast, provides limited exposure and may not allow sufficient abdominal access if bleeding develops (Horowitz, 2003).

3. **Abdominal Exploration.** Para-aortic lymph nodes should be palpated routinely during initial abdominal exploration. A hand is placed beneath the small bowel mesentery to palpate the aorta. The index and middle fingers then are used to straddle the aorta and palpate for lymphadenopathy. Suspicious or grossly positive para-aortic nodes typically should be removed as one of the initial steps in the abdominal operation. Unexpected positive nodes may indicate that the proposed operative plan should be abandoned or revised (Whitney, 2000). For the majority of instances when no adenopathy is present, the dissection usually should be performed last because of the possibility of triggering catastrophic bleeding that otherwise might limit further surgery.

4. **Visualization.** Exposure and proper retractor positioning are perhaps the most important parts of the procedure. Thus, a self-retaining retractor is positioned to allow access to the aorta. The sigmoid colon should be gently retracted in a lower left direction, whereas small bowel and transverse colon are packed with laparotomy sponges into the upper abdomen. Modified Trendelenburg patient positioning is also helpful to shift bowel from the operative field. Additional sharp dissection along the right paracolic gutter may be necessary to sufficiently mobilize and move the cecum from the dissection plane. Once bowel has been cleared from the field, the peritoneum overlying the aorta and right common iliac artery should be visible. Both vessels should be palpated before proceeding.

5. **Opening the Retroperitoneal Space.** As described in Section 43-1, Radical Abdominal Hysterectomy (Type III), Step 5, the ureter is isolated and held laterally on a Penrose drain. A right-angle clamp is used to guide electrosurgical blade dissection of the posterior peritoneum in a medial direction over the right common iliac artery and aorta (Fig. 43-10.1). Staying directly above these arteries is a safe location because no vital structures cross these vessels medial to the ureter. The surgeon stops intermittently to palpate the course of the artery before continuing dissection in a cephalad direction to the inferior duodenal fold. Blunt dissection is performed to mobilize the duodenum, and the cephalad self-retaining retractor blade is repositioned to retract this bowel.

FIGURE 43-10.1



Source: Schorge JO, Schaffer JI, Halvorson LM, Hoffman BL, Bradshaw KD, Cunningham FG: *Williams Gynecology*: http://www.accessmedicine.com

Opening the retroperitoneal space.

6. **Exposing the Aorta and Inferior Vena Cava.** The surgeon returns to the area near the right ureter, where the posterior peritoneal dissection began. Electrosurgical cutting is used to incise the areolar sheath on top of the right common iliac artery, and dissection is continued proximally past the aortic bifurcation to the inferior mesenteric artery (IMA). Small perforating vessels may be encountered and coagulated.

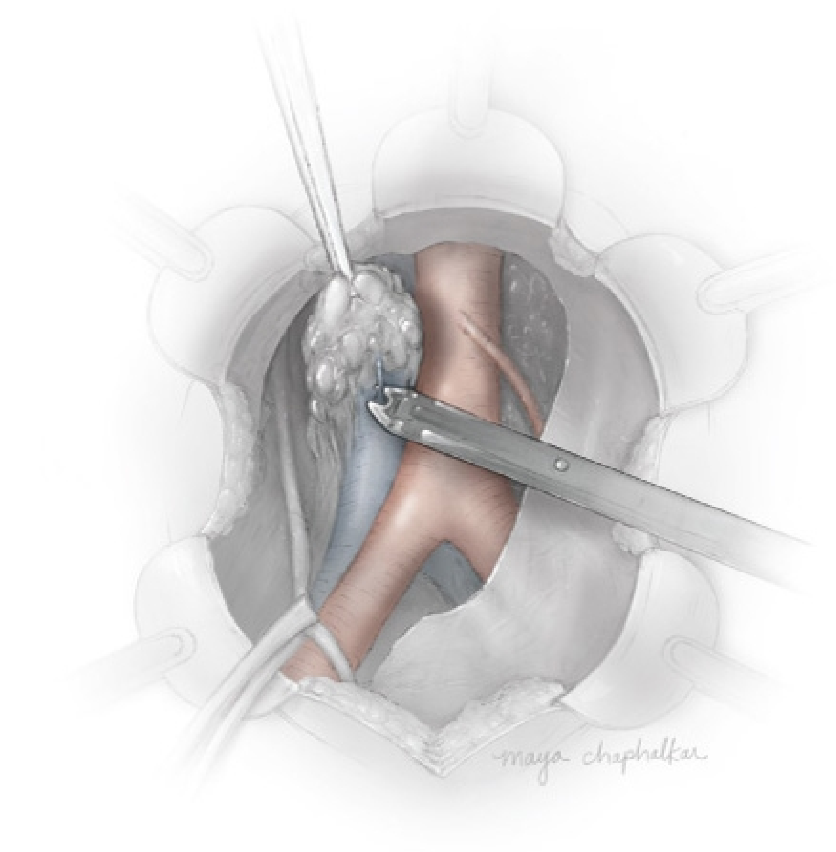
7. **Removal of Right Para-aortic Nodes.** Lymphadenectomy begins lateral to the midportion of the right common iliac artery. The ureter is held medially by traction on the Penrose drain while the nodal bundle is elevated with forceps and blunt dissection is performed to better visualize its fibrinous attachments to the distal artery.

   A right-angle clamp is placed under these fibers, and electrosurgical cutting is used to divide them. Blunt dissection will

demonstrate the right common iliac vein as it crosses beneath the artery. The adventitial sheath surrounding the common iliac vein is incised and extended upward by following the arterial direction to the level of the IMA. The lateral border of dissection is established by holding the ureter laterally and bluntly separating the lateral side of the inferior vena cava (IVC) from the retroperitoneal fat. The upper right abdominal retractor blade may need to be repositioned to improve visibility.

At this point, the right para-aortic node bundle has been largely detached medially, distally, and laterally. Lymph nodes are grasped distally with Debakey forceps and elevated to identify perforating veins from the IVC as gentle blunt dissection is performed in a proximal direction. The delicate nature of arterial and venous branches along the aorta and IVC warrant meticulous dissection to reduce bleeding. The "fellow's vein" is encountered routinely near the level of the aortic bifurcation and should be occluded with a vascular clip for hemostasis (Fig. 43-10.2). The nodal bundle can be removed by placing large vascular clips across the proximal end and transecting it.

FIGURE 43-10.2

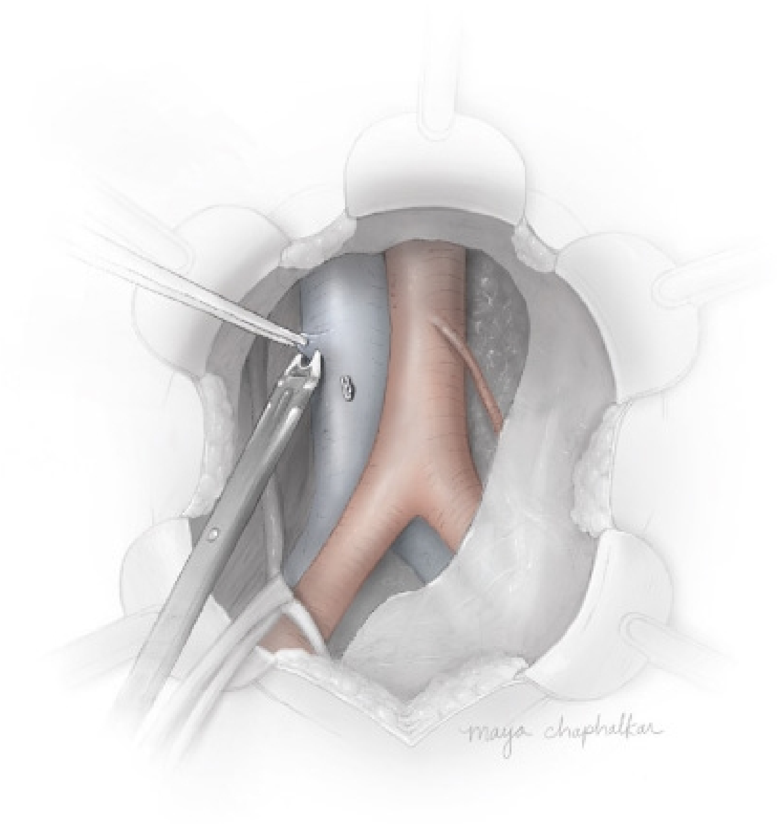


Source: Schorge JO, Schaffer JI, Halvorson LM, Hoffman BL, Bradshaw KD, Cunningham FG: *Williams Gynecology*: http://www.accessmedicine.com

Removal of right para-aortic nodes.

8. **Repair of Venous Bleeding.** The surgeon should prepare for small lacerations in the wall of the IVC or common iliac veins by inadvertent avulsion of perforating venous tributaries. Hemorrhage may be copious and immediate. Initially, pressure is applied with a sponge stick or finger. Second, exposure is assessed. Blood is suctioned from the abdominal cavity, retractors are repositioned, and incisions are extended if necessary. Lastly, proper vascular instruments are obtained. Venous bleeding usually can be repaired simply with vascular clips (Fig. 43-10.3).

FIGURE 43-10.3



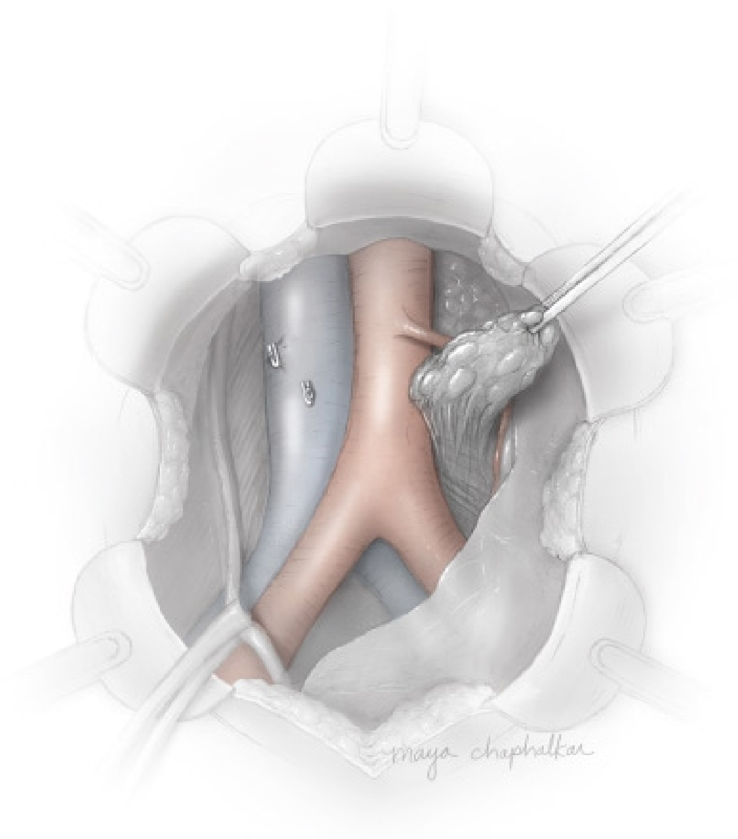
Source: Schorge JO, Schaffer JI, Halvorson LM, Hoffman BL, Bradshaw KD, Cunningham FG: *Williams Gynecology*: http://www.accessmedicine.com

Repair of venous bleeding.

9. **Removal of Left Para-aortic Nodes.** The upper left abdominal retractor blade is repositioned under the posterior peritoneal edge to access the left side of the aorta. Electrosurgical dissection is performed to incise the adventitial sheath of the aorta distally to the midportion of the left common iliac artery. Lateral blunt dissection at the level of the bifurcation should demonstrate the left ureter and establish this lateral boundary. Blunt posterior dissection is performed directly adjacent to the left side of the aorta to develop the medial plane between the nodal bundle and aorta. This dissection is continued to the vertebral bodies and then extended distally to the midportion of the left common iliac artery.

   The nodal bundle is held on traction to aid vascular clip placement and distal transection unless already freed by proximal dissection during a preceding pelvic lymphadenectomy. Nodal tissue is elevated and progressively lifted proximally while alternating blunt and electrosurgical dissection is performed to divide any remaining posterior attachments (Fig. 43-10.4). The dissection is continued cephalad to the IMA, where the nodal bundle is clipped and transected.

FIGURE 43-10.4



Source: Schorge JO, Schaffer JI, Halvorson LM, Hoffman BL, Bradshaw KD, Cunningham FG: *Williams Gynecology*: http://www.accessmedicine.com

Removal of left para-aortic nodes.

10. **Removal of Interiliac Nodes.** Optionally, several additional lymph nodes may be removed by excising the fatty interiliac tissue. The posterior peritoneum at the aortic bifurcation is grasped, and electrosurgical dissection is performed along the inner side of both common iliac arteries. The crossing left common iliac vein is visible directly beneath. Blunt dissection is performed along the surface of the vein because there are typically a few small perforating vessels. Electrosurgical dissection can be used from right to left after a triangle-shaped area of fatty lymphoid tissue has been mobilized between the common iliac arteries.

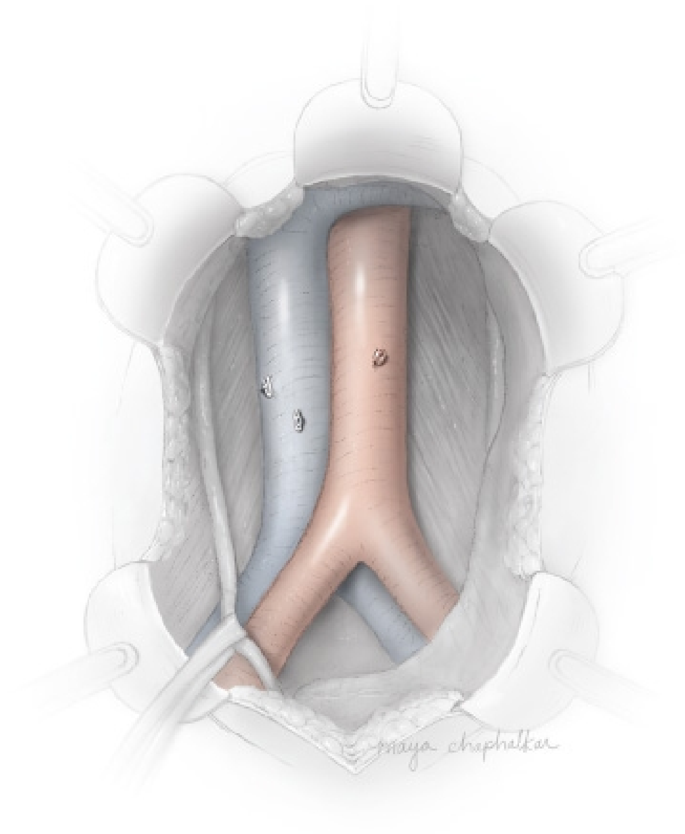
11. **High Para-aortic Lymphadenectomy.** Additionally, a surgeon may elect an extended dissection during ovarian cancer staging or when palpable lymphadenopathy is noted during uterine cancer surgery (Morice, 2003). The anatomic boundaries begin distally at the IMA and reach proximally to the entry level of the right ovarian vein and left renal vein (see Fig. 38-15). (Whitney, 2005).

    The midline peritoneal incision is incised more proximally, and the duodenal loop is dissected bluntly off the aorta and IVC. Repositioning of the retractor blade to retract this loop aids exposure. The right-sided para-aortic nodal bundle is regrasped with Debakey forceps, and dissection is continued proximally until the ovarian vein can be clipped and divided.

    Dissection of the left side begins with identification, clipping, and cutting of the IMA. This maneuver allows access to upper nodal tissue. The proximal boundary is established by blunt dissection to visualize the left renal vein. Removal of the left para-aortic nodes includes elevating the distal nodal bundle, performing blunt dissection to isolate and electrosurgically

coagulate lymphatic attachments, and progressing toward the renal vein, where the bundle is clipped and transected (Fig. 43-10.5).

FIGURE 43-10.5



Source: Schorge JO, Schaffer JI, Halvorson LM, Hoffman BL, Bradshaw KD, Cunningham FG: *Williams Gynecology*: http://www.accessmedicine.com

High para-aortic lymphadenectomy.

12. **Retroaortic Lymphadenectomy.** This more extended dissection is optional and begins after left-sided para-aortic lymphadenectomy has been completed. The left-sided lumbar arteries can be visualized branching directly from the aorta. These vessels may be clipped and cut to allow manual rolling of the aorta from left to right and allow access to the retroaortic nodal chain. Typically, this procedure is performed when imaging studies have demonstrated suspicious nodes in the region.

13. **Final Steps.** Gauze sponges may be opened and gently placed in areas of nodal dissection to tamponade any surface oozing. There is no benefit to closing the retroperitoneal space or routinely using suction drainage (Morice, 2001).

Postoperative

The postoperative course following para-aortic lymphadenectomy in general follows that after laparotomy. However, the incidence of postoperative ileus is increased owing to longer operative time, increased bowel manipulation, extension of the incision, and additional blood loss. Most episodes will be mild, but longer hospital stays may be expected (Fujita, 2005).

43-11 EN BLOC PELVIC RESECTION

Ovarian cancer with contiguous encasement of the reproductive organs, pelvic peritoneum, cul-de-sac, and sigmoid colon is the main indication for en bloc pelvic resection, which is also known as *radical oophorectomy.* This effective technique aids a maximal cytoreductive surgical effort. As a result, removal of all microscopic and infiltrative peritoneal tumor in the pelvis has been associated with improved survival in women with advanced epithelial ovarian cancer (Aletti, 2006b). Moreover, pelvic recurrence rates are very lowâ€"reflecting the completeness of pelvic tumor eradication (Hertel, 2001). Many of the principles of en bloc pelvic resection mirror those of other procedures in gynecologic oncology.

Preoperative

PATIENT EVALUATION

Pelvic examination may show a relatively immobile mass, and abdominal-pelvic computed tomographic (CT) scanning typically demonstrates a pelvic mass and ascites. With the presumed diagnosis of advanced ovarian cancer, patients are prepared preoperatively for anticipated cytoreductive surgery. However, the need for en bloc resection usually is dictated by intraoperative findings rather than preoperative testing.

CONSENT

In general, women with advanced ovarian cancer undergoing cytoreductive surgery are at significant risk for complications, and they should be counseled accordingly. In one series of en bloc resections, 29 percent of patients required blood transfusion; 36 percent had minor postoperative complications such as incisional cellulitis, urinary tract infection, or ileus; and 13 percent had major postoperative complications such as pulmonary embolism, sepsis, or upper gastrointestinal hemorrhage (Bristow, 2003). Additional specific risks of en bloc resection that should be discussed include anastomotic leaks and fistulas (Park, 2006).

PATIENT PREPARATION

Primary anastomosis without colostomy is typical for most patients. Thus, bowel preparation is mandatory for any type of cytoreductive ovarian cancer surgery but particularly if en bloc pelvic resection is a possibility. One or more bowel resections may be required to achieve optimal debulking, and often, preoperative determination of the exact location of tumor infiltration is not easy. Pneumatic compression devices or subcutaneous heparin is particularly important due to the anticipated longer operation length and postoperative recovery (see Chap. 39, Prophylaxis Options). Moreover, patients should be typed and crossed routinely for packed red blood cell replacement.

Intraoperative

INSTRUMENTS

En bloc pelvic resection requires access to multiple sizes of bowel staplers, including gastrointestinal anastomosis (GIA), transverse anastomosis (TA), and end-to-end anastomosis (EEA) staplers. Additionally, a ligate-divide-staple (LDS) device may be used to divide vascular tissue pedicles.

Surgical Steps

1. **Anesthesia and Patient Positioning.** Bimanual examination under general anesthesia is especially important to confirm the necessity of leg positioning in Allen stirrups. Access to the perineum is crucial any time the EEA device may need to be placed in the rectum. Sterile preparation of the abdomen, perineum, and vagina is performed, and a Foley catheter is placed.

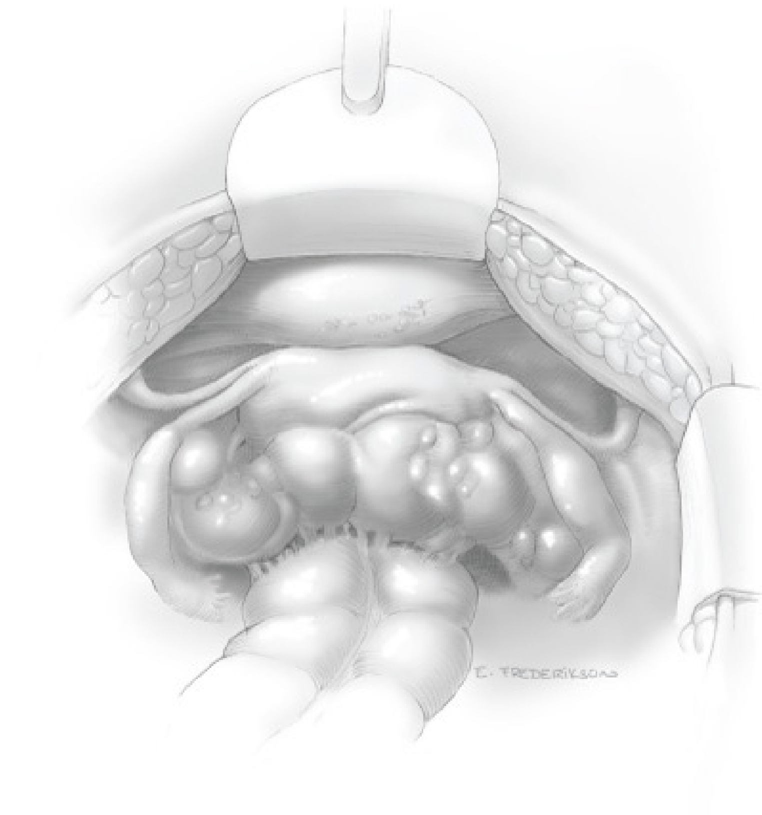
2. **Abdominal Entry.** Typically, a vertical incision is selected for ovarian cancer debulking surgery because the extent of disease cannot be known precisely beforehand. Debulking may require access to the diaphragm and other upper abdominal structures.

3. **Exploration.** The abdomen is explored thoroughly to first determine whether all gross disease can be removed safely. For example, unresectable upper abdominal tumor makes the prospect of a radical pelvic operation less attractive.

   Frequently during exploration, it is difficult to distinguish uterus, adnexa, and adjacent tumor. In Fig. 43-11.1, both ovaries

are grossly enlarged with tumor and are densely fixed into the posterior cul-de-sac with contiguous involvement of the uterus, rectosigmoid, and lateral sidewalls. Moreover, superficial implants coat the fallopian tubes, the vesicouterine fold, and much of the surrounding pelvic peritoneum. En bloc pelvic resection will allow removal of all gross disease.

FIGURE 43-11.1



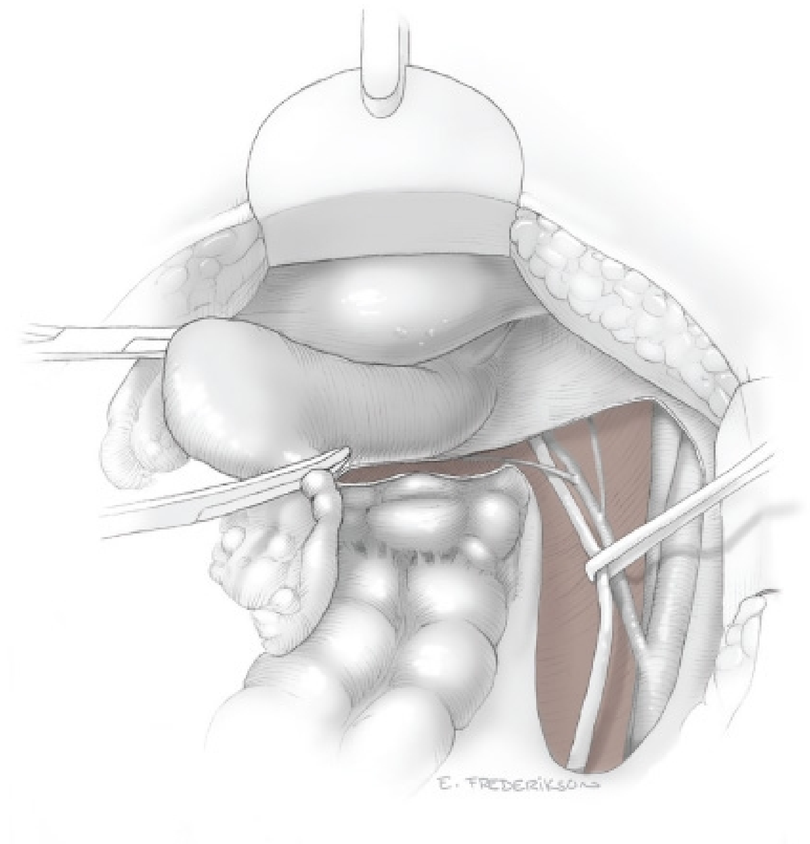
Source: Schorge JO, Schaffer JI, Halvorson LM, Hoffman BL, Bradshaw KD, Cunningham FG: *Williams Gynecology*: http://www.accessmedicine.com

Extensive ovarian cancer.

4. **Lateral Pelvic Dissection.** The lateral peritoneum is grasped with an Allis clamp, and an electrosurgical blade is used to enter the retroperitoneal space if the round ligaments cannot be located with certainty (Fig. 43-11.2). The loose areolar connective tissue of this space is dissected bluntly. The overlying peritoneum is incised sharply to create an opening in which the external iliac artery can be palpated. This artery is followed bluntly to the bifurcation with the internal iliac artery. The medial peritoneal leaf of the broad ligament is elevated to identify the ureter, around which a 1/4 -in Penrose drain is looped.

   The infundibulopelvic (IP) ligament typically will not be entirely distinguishable because of induration and anatomic distortion by tumor. A window is opened bluntly just superior to the ureter as it crosses above the pelvic brim to isolate a tissue pedicle that will include the IP ligament. The ligament is isolated, clamped, cut, and tied with 0-gauge delayed-absorbable suture before repeating the entire sequence on the contralateral side. The ureter then may be mobilized distally, and the anterior portion of the broad ligament is incised toward the vesicouterine fold using an electrosurgical blade. The round ligament will be identified during this dissection and divided separately.

FIGURE 43-11.2

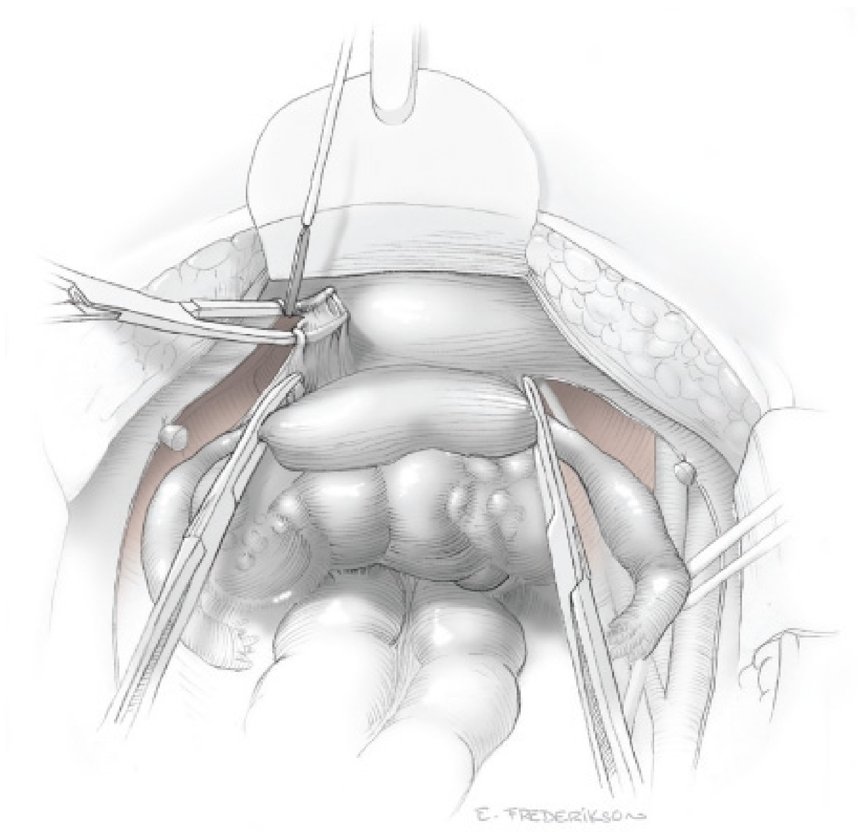


Source: Schorge JO, Schaffer JI, Halvorson LM, Hoffman BL, Bradshaw KD, Cunningham FG: *Williams Gynecology*: http://www.accessmedicine.com

Lateral pelvic dissection.

5. **Vesicouterine Dissection.** The anterior broad ligament dissection is continued with a right-angle clamp guiding the electrosurgical blade (Fig. 43-11.3). The peritoneum typically is edematous and thickened. En bloc removal of tumor implants within the vesicouterine fold will require a wide excision of the peritoneum over the dome of the bladder. Thus, the proximal end of the vesicouterine fold may be held on traction, and an electrosurgical blade may be used to dissect sharply in a caudal direction toward the cervix while encompassing the tumor. The bladder mucosa typically is not entered but may be simply repaired if an inadvertent cystotomy occurs (see Fig. 40-40). The whitish cervix will be seen, and the bladder then may be advanced distally in the usual manner. The ureters are held laterally while the uterine vessels are freed of surrounding connective tissue (skeletonized), clamped, cut, and ligated.

FIGURE 43-11.3

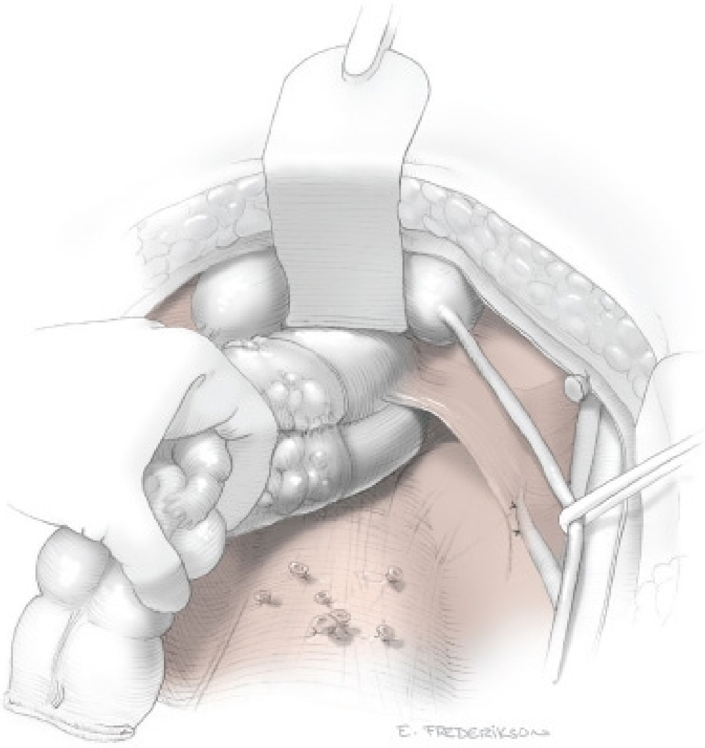


Source: Schorge JO, Schaffer JI, Halvorson LM, Hoffman BL, Bradshaw KD, Cunningham FG: *Williams Gynecology*: http://www.accessmedicine.com

Vesicouterine dissection.

6. **Dividing the Sigmoid.** The ureters are held laterally while a right-angle clamp guides electrosurgical blade dissection of the posterior peritoneum to the sigmoid mesentery. The sigmoid segment that lies proximal to the tumor is selected, and the underlying mesentery is incised superficially with an electrosurgical blade on each side. A GIA stapler is inserted to divide the bowel. The remaining mesentery is scored superficially with an electrosurgical blade and divided with the LDS (small pedicles) or clamps and ties (larger pedicles). The inferior mesenteric artery (IMA) branches are the largest vessels encountered. These are clamped, cut, and ligated separately. The avascular retrorectal space between the rectum and the sacrum then may be dissected bluntly to completely mobilize the rectosigmoid down to the cervix (Fig. 43-11.4).

FIGURE 43-11.4

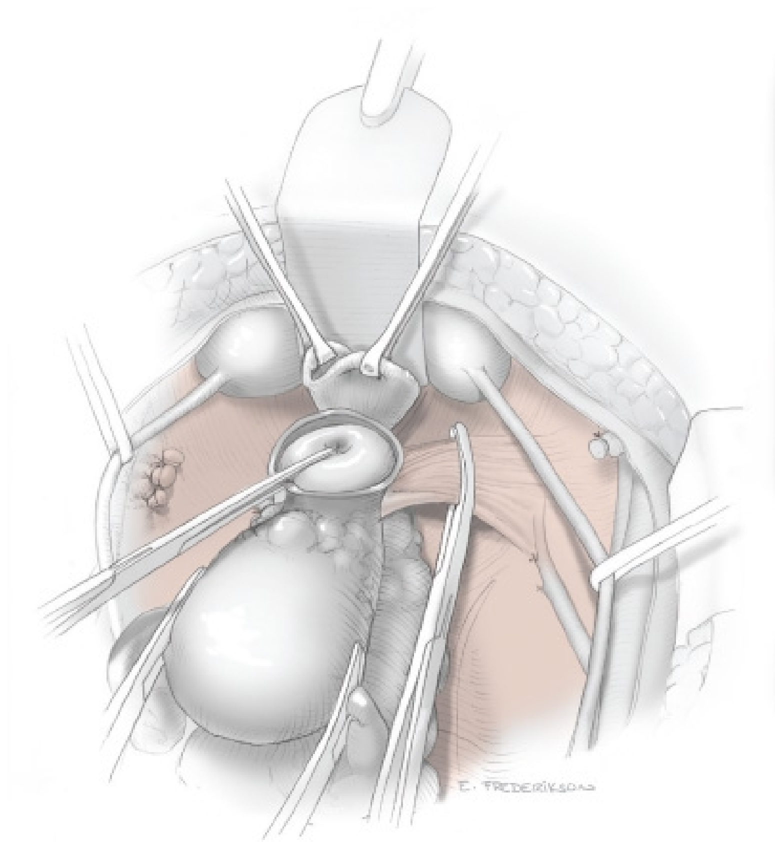


Source: Schorge JO, Schaffer JI, Halvorson LM, Hoffman BL, Bradshaw KD, Cunningham FG: *Williams Gynecology*: http://www.accessmedicine.com

Dividing the rectosigmoid.

7. **Retrograde Hysterectomy.** The bladder is advanced distally onto the upper vagina with sharp electrosurgical blade dissection. The distal anterior vaginal wall is grasped with a Kocher clamp. The anterior vaginal wall then is incised at 12 o'clock with an electrosurgical blade, and the incision is extended laterally to the right and left. The cervix is grasped with a Kocher clamp and retracted to expose the posterior vaginal wall. An electrosurgical blade is used to incise this wall transversely and enter the rectovaginal space. An Allis clamp is placed on the proximal edge of the anterior and posterior vagina to apply caudad traction and reduce bleeding. A retrorectal hand is placed to assess whether the tumor extends into the rectovaginal septum beyond the cervix. With large masses, distal dissection may be required into the rectovaginal septum to reach a point distal to the tumor's leading edge. Alternatively, smaller tumors may allow proximal dissection in the rectovaginal septum. This gains additional rectal length distal to the tumor and allows for creation of a higher anastomosis. Finally, the remaining uterosacral and cardinal ligaments are clamped in a retrograde fashion while confirming lateral ureteral positioning (Fig. 43-11.5).

FIGURE 43-11.5



Source: Schorge JO, Schaffer JI, Halvorson LM, Hoffman BL, Bradshaw KD, Cunningham FG: *Williams Gynecology*: http://www.accessmedicine.com

Retrograde hysterectomy.

8. **Distal Rectal Division.** The mucosa of the rectal segment distal to the tumor is circumferentially dissected free of mesenteric attachments and rectal pillars by constant traction on the en bloc specimen (Fig. 43-11.6). The TA stapler is inserted into the pelvis and fired to transect the rectum and lift the uterus, adnexa, rectosigmoid, and surrounding peritoneum out of the pelvis. The vaginal opening then may be closed in a running fashion with 0-gauge delayed-absorbable suture (Fig. 43-11.7).

FIGURE 43-11.6

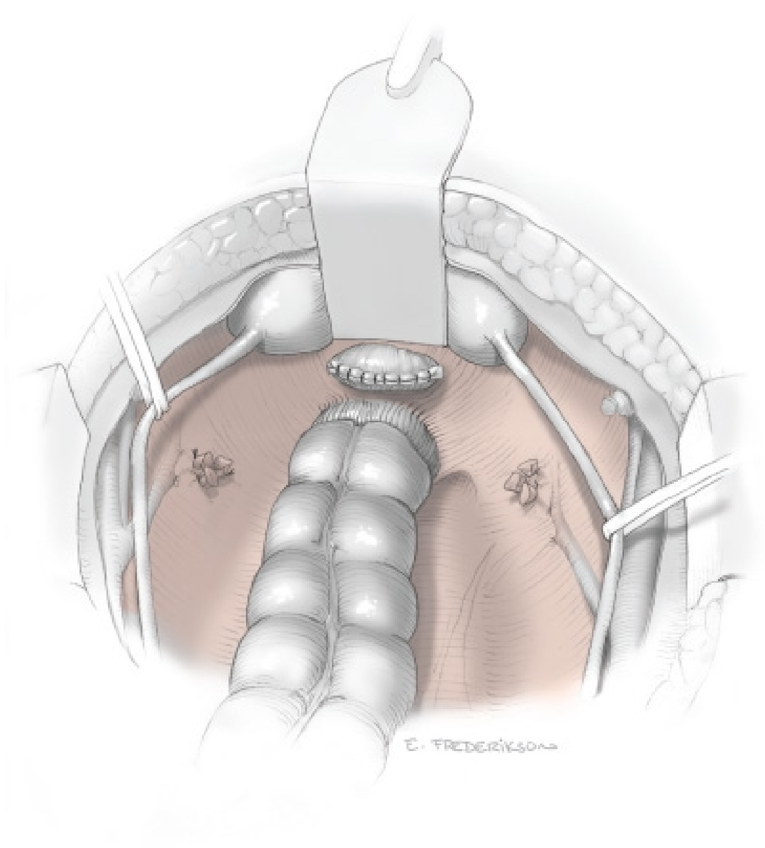
Rectosigmoid resection.

FIGURE 43-11.7



Source: Schorge JO, Schaffer JI, Halvorson LM, Hoffman BL, Bradshaw KD, Cunningham FG: *Williams Gynecology*: http://www.accessmedicine.com

Final appearance.

9. **Final Steps.** The surgeon then will proceed with additional procedures if necessary to complete the ovarian cancer debulking surgery. A colostomy or rectosigmoid anastomosis may require mobilization of the splenic flexure and is performed near the end of surgery (see Sections 43-15, Colostomy and 43-19, Low Anterior Resection). Postoperative drains may be placed at the surgeon's discretion. Occasionally, the bladder also may require testing to exclude inadvertent injury during vesicouterine dissection. All pedicle sites should be rechecked for hemostasis.

Postoperative

En bloc pelvic resection of primary and recurrent ovarian cancer permits a high rate of complete debulking with acceptable morbidity and mortality rates (Park, 2006). Urinary tract infection, pneumonia, deep venous thrombosis, wound cellulitis, and postoperative ileus are relatively common events following major abdominal surgery for ovarian cancer. Reoperation for anastomotic breakdown or postoperative hemorrhage specific to en bloc pelvic resection should be uncommon (Bristow, 2003; Clayton, 2002).

43-12 OMENTECTOMY

The omentum typically is removed for two reasons: tumor debulking or cancer staging. Patients who present with advanced ovarian cancer almost invariably have metastases to the omentum. The extent of this "omental cake" often is difficult to appreciate on imaging studies, and a tumor may be massive and involve the upper gastrocolic ligament, anterior abdominal wall, splenic hilum,

and transverse colon (see Fig. 35-16). Thus, the surgeon should be prepared to encompass the entire tumor with an adequate resection.

Omentectomy is also indicated routinely for staging patients with ovarian cancer or with uterine papillary serous carcinoma who do not have obvious metastatic disease (Geisler, 1999). Infracolic (below the transverse colon) omentectomy is sufficient for most clinical circumstances, but supracolic (total) omentectomy may be indicated for a large omental cake.

Preoperative

PATIENT EVALUATION

Imaging studies may suggest the presence of an omental cake, but the extent is difficult to ascertain until exploration in the operating room.

CONSENT

Although bleeding may follow inadequate vessel ligation, complications from omentectomy are rare. Obesity and intra-abdominal adhesive disease, however, may increase these risks. Obesity results in a much thicker omentum and resulting thicker vascular pedicles that may slip from clamps or ligatures. Additionally, prior upper abdominal surgeryâ€”particularly gastric bypassâ€”may cause adhesions and a more difficult resection. In addition to these risks, women with an omental cake should be informed of a possible need for bowel resection, splenectomy, or other radical debulking procedure to remove an entire tumor.

PATIENT PREPARATION

Bowel preparation should be performed when an omental cake is present because of the possibility of colon resection. The risk of infection following omentectomy is low. However, this surgery typically is performed with other gynecologic procedures that warrant antibiotic prophylaxis.

Intraoperative

Surgical Steps

1. **Anesthesia and Patient Positioning.** Omentectomy typically is performed as an inpatient procedure under general anesthesia. The patient is positioned supine, a Foley catheter is placed, and the abdomen is surgically prepared.

2. **Abdominal Entry.** Infracolic omentectomy may be performed through any type of incision. However, because of the uncertain extent of disease that accompanies these cases, a midline vertical incision is selected most commonly.

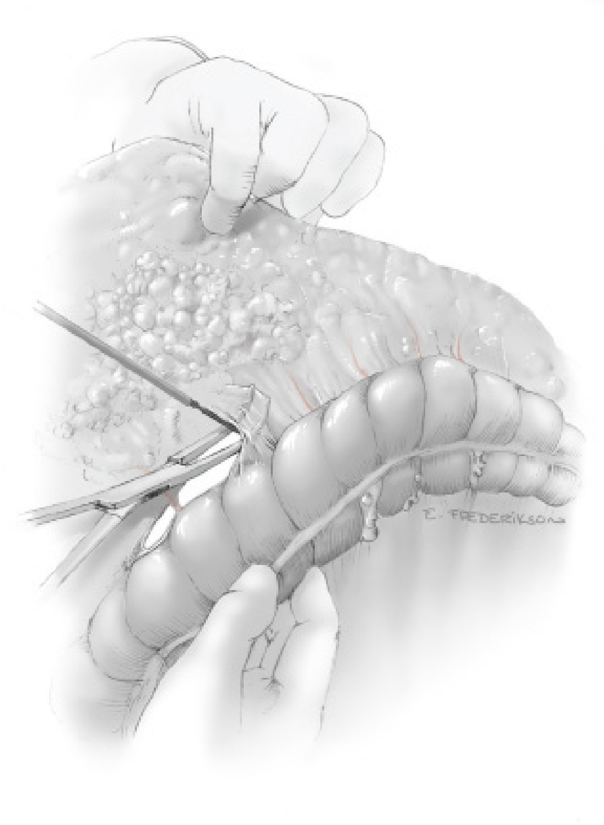
3. **Exploration.** Palpation of the omentum is often the first step in exploring the abdomen. This organ is directly beneath a midline vertical incision and should be readily visible. Omentectomy typically is the first procedure performed in women with an omental cake and presumed ovarian cancer. The omentum usually can be removed quickly and sent for frozen-section analysis while the surgeon places a self-retaining retractor and proceeds with the remaining planned operation.

4. **Visualization.** The surgeon gently grasps the infracolic omentum and pulls it out of the abdomen through the incision. The borders of any omental cake can be seen directly or palpated. The extent of resection then can be determined. If necessary, the abdominal wall incision can be extended.

5. **Entrance into the Lesser Sac.** The posterior leaf of the omentum is attached to the transverse colon primarily by filmy adventitial tissue with some intervening small vessel tributaries. These attachments can be cut and coagulated electrosurgically to enter the lesser sac (Fig. 43-12.1). Dissection generally begins as far to the right as possible and continues as far to the left as possible. An open right-angle clamp guides the direction of the electrosurgical blade.

   Entrance into the lesser sac mobilizes the colon and provides access to the tumor-free proximal gastrocolic ligament. The omentum then is flipped over and held on distal traction.

FIGURE 43-12.1



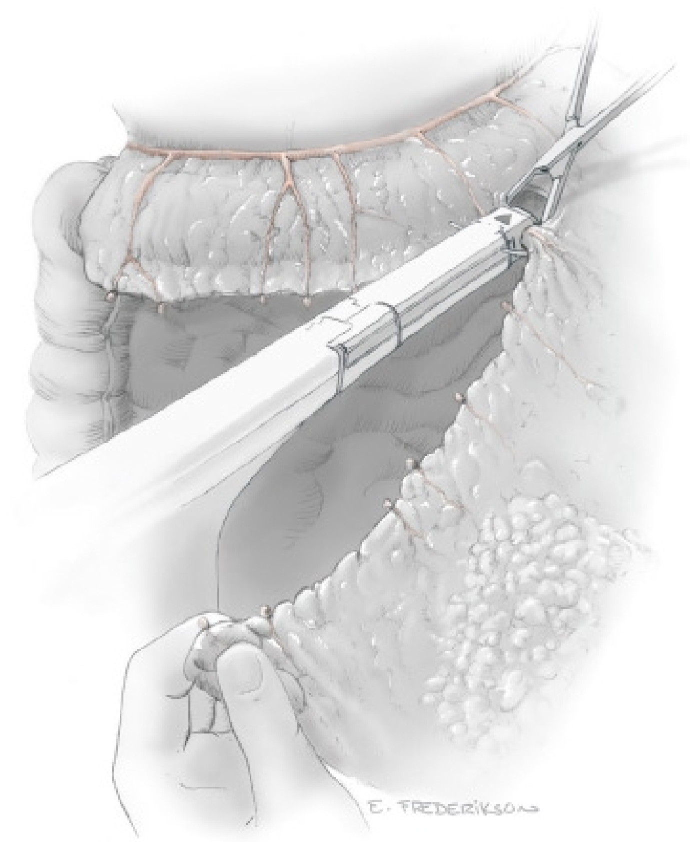
Source: Schorge JO, Schaffer JI, Halvorson LM, Hoffman BL, Bradshaw KD, Cunningham FG: *Williams Gynecology*: http://www.accessmedicine.com

Posterior dissection to enter the lesser sac.

6. **Gastrocolic Ligament Division.** Dissection again generally begins on the far right. Numerous vertically coursing vessels can be seen, but others are covered by fatty tissue and difficult to appreciate. A right-angle clamp is used by the surgeon to "pop" through an avascular portion of the gastrocolic ligament that is near to but safely distal from the colon. The clamp then is opened in a vertical direction (parallel to the vessels) and held in place to guide the LDS (linear dissecting stapler) (Fig. 43-12.2). This stapler incises tissues between its jaws and applies a row of fine vascular staples on both sides of the incision. The LDS is ideal because it is much faster than doubly clamping each pedicle of the gastrocolic ligament and placing individual suture ligatures.

   This procedure is continued across the entire gastrocolic ligament. Each pedicle of tissue is either divided with the LDS or is coagulated and cut electrosurgicallyâ€”depending on the apparent vascularity of the tissue. The omentum will need to be rotated back and forth intermittently to make certain that dissection remains away from the colon.

FIGURE 43-12.2



Source: Schorge JO, Schaffer JI, Halvorson LM, Hoffman BL, Bradshaw KD, Cunningham FG: *Williams Gynecology*: http://www.accessmedicine.com

Anterior ligation of gastrocolic ligament.

7. **Total Omentectomy.** In patients in whom an omental cake has extended proximally, supracolic (total) omentectomy is indicated. This procedure requires a midline vertical incision to provide better exposure to the upper abdomen. Resection simply may involve transecting the omentum at a higher level in the gastrocolic ligament. Alternatively, anatomic boundaries of resection may need to be extended to the hepatic flexure, the stomach, and the splenic flexure to encompass the entire tumor.

   Dissection again proceeds from right to left. Mobilization of the ascending colon around the hepatic flexure may be necessary. The right gastroepiploic artery is ligated with an LDS, and the dissection is continued to the left by dividing the short gastric vessels until the lateral-most portion of the tumor is reached. Mobilization of the descending colon and takedown of the splenic flexure may be required if tumor extends that far laterally. The omentum then is removed from the transverse colon by LDS ligature across the remaining gastrocolic ligament.

8. **Incision Closure.** The omentum should be re-examined at completion of surgery before closing the abdomen. Occasionally, small bleeding vessels or a hematoma will need to be addressed with additional ligation. The abdominal entry incision then is closed as described in Sections 41-1, Midline Vertical Incision or 41-2, Pfannenstiel Incision.

Postoperative

Nasogastric tube placement is required only if a total omentectomy has been performed. Decompression of the stomach for 48

hours protects the ligated gastric vessels from postoperative dislodgement from to gastric dilation. The remaining postoperative course follows that for laparotomy or for other specific concurrent surgeries performed.

43-13 SPLENECTOMY

In gynecologic oncology, removal of the spleen is required occasionally to achieve optimal surgical cytoreduction of metastastic ovarian cancer (Magtibay, 2006). Most commonly, tumor is found extending directly from the omentum into the splenic hilum during primary debulking surgery. Although splenectomy and other extensive upper abdominal resection techniques have been shown to improve survival, only 1 percent of patients actually will have their spleen removed during the initial operation (Eisenhauer, 2006; Goff, 2006). Splenectomy also is indicated for selected patients with isolated parenchymal recurrences to assist optimal secondary surgical cytoreduction of ovarian cancer (Chen, 2000). Lastly, intraoperative splenic trauma is the least common indication and is often unanticipated (Magtibay, 2006).

Preoperative

PATIENT EVALUATION

Preoperative diagnosis of splenic involvement is often difficult to predict prior to primary cytoreduction (Chen, 2000). Typically, in such cases, an omental cake is seen on computed tomographic (CT) scan, but its proximity to the spleen is difficult to ascertain. Splenic involvement is more commonly distinguishable at the time of secondary cytoreduction. Ideally, relapsed patients have isolated disease and an extended progression-free survival of at least 12 months before they are considered for splenectomy.

CONSENT

Patients with presumed advanced ovarian cancer should be consented for possible splenectomy, although the decision to perform the procedure will be finalized only intraoperatively. Removal of the spleen results in a longer operative time, greater blood loss, and longer hospital stay but ultimately may determine whether tumor is debulked optimally or not (Eisenkop, 2006). Possible complications include hemorrhage, infection, and pancreatitis.

Intraoperative

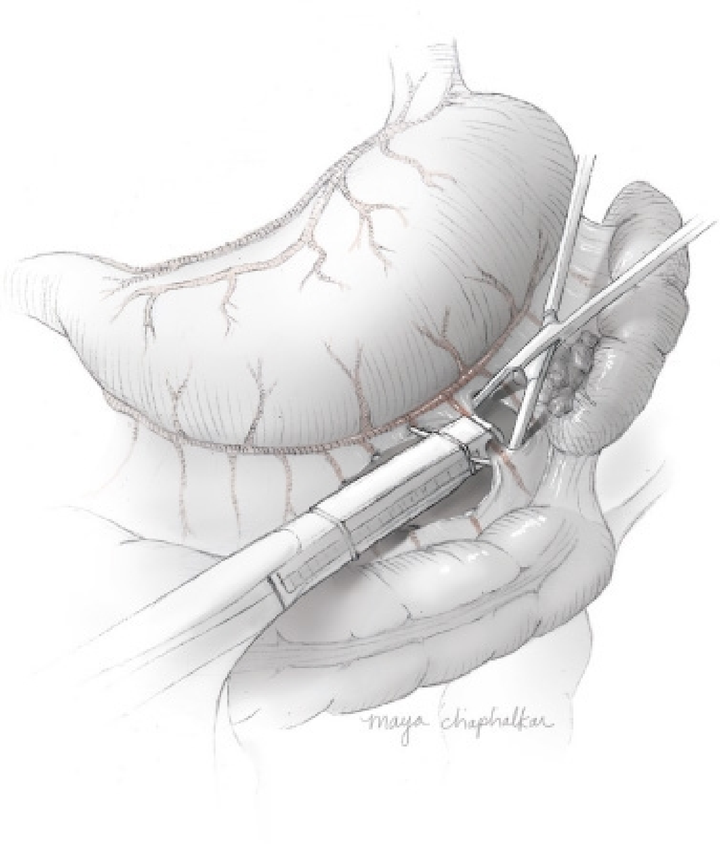
Surgical Steps

1. **Anesthesia and Patient Positioning.** Splenectomy is performed under general anesthesia and with the patient supine. As with other major intra-abdominal surgery, the abdomen is surgically prepared, and a Foley catheter is inserted.

2. **Abdominal Entry and Exploration.** Splenectomy generally requires a vertical incision for adequate exposure. Following entry, a surgeon should carefully assess the entire abdomen and pelvis to confirm the ability to resect all gross disease. Ideally, splenectomy is performed only if optimal tumor debulking can be achieved. The spleen is grasped to assess its mobility, degree of tumor involvement, and potential difficulty in removal.

3. **Entrance into the Lesser Sac.** The gastrocolic ligament is opened to the left of midline by dividing vascular pedicles with a ligate-divide-staple (LDS) device and transecting avascular filmy attachments with an electrosurgical blade. Dissection with the LDS stapler is continued in two directions: (1) superiorly to the transverse colon toward the splenocolic ligament and (2) inferiorly to the greater curvature of the stomach toward the gastrosplenic ligament (Fig. 43-13.1). The intervening portion of omentum often is involved with tumor.

FIGURE 43-13.1



Source: Schorge JO, Schaffer JI, Halvorson LM, Hoffman BL, Bradshaw KD, Cunningham FG: *Williams Gynecology*: http://www.accessmedicine.com

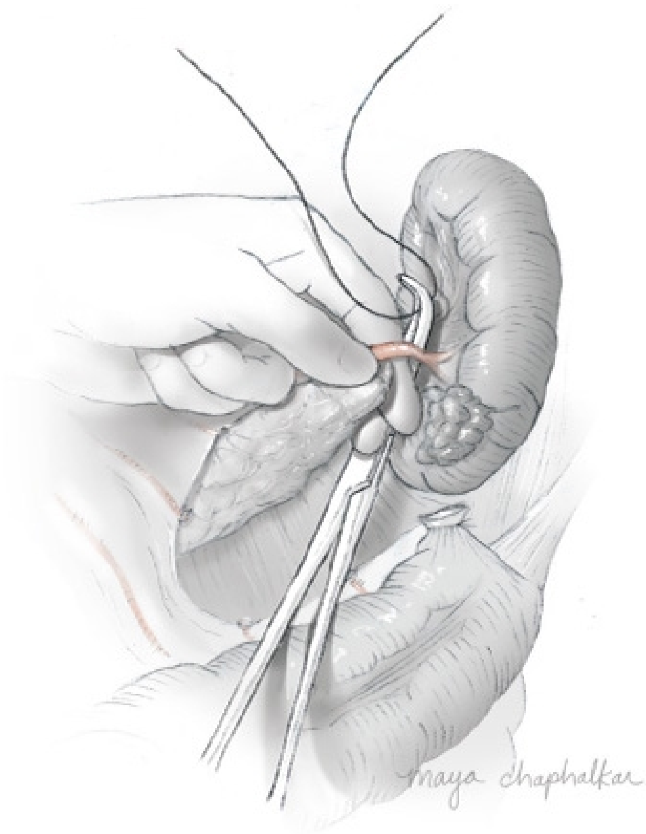
Mobilizing the spleen.

4. **Mobilization of the Spleen.** The spleen is grasped, elevated, and pulled medially to expose the splenophrenic ligament. The surgeon uses alternating electrosurgical blade and blunt finger dissection to mobilize the spleen. Additional blunt and sharp dissection then is performed circumferentially to free the spleen from the gastrosplenic and splenocolic ligaments.

5. **Ligating the Splenic Vessels.** The spleen is elevated into the incision, and the peritoneum overlying the splenic hilum then is incised carefully. To facilitate this approach, a left index finger is held against the spleen, and a thumb holds the pancreatic tail out of the dissecting plane. The pancreatic tail lies close to the splenic hilumâ€”often within 1 cm.

   Blunt dissection parallel to the expected course of the splenic artery and vein aids identification of these vessels. The artery, vein, and vascular tributaries should be ligated individually. The artery is isolated first to prevent splenic engorgement (Fig. 43-13.2). A right-angle clamp is placed beneath the artery, and a 2-0 silk suture is pulled through and tied. A second silk tie is placed more distally, directly at the hilum. The proximal end of the artery again is tied or occluded with a vascular clip. The artery then is divided, and the procedure is repeated for the splenic vein. Vascular tributaries should be divided similarly. The remaining peritoneal attachments are incised with an electrosurgical blade to remove the spleen.

FIGURE 43-13.2



Source: Schorge JO, Schaffer JI, Halvorson LM, Hoffman BL, Bradshaw KD, Cunningham FG: *Williams Gynecology*: http://www.accessmedicine.com

Vessel ligation.

6. **Final Steps.** The distal pancreas should be inspected carefully to exclude injury. The splenic vessels also should be re-examined prior to abdominal closure. Suspicion of trauma or bleeding should prompt placement of a suction drain in the splenic bed. Otherwise, drainage is not required routinely. A nasogastric tube is placed to decompress the stomach and prevent displacement of gastric vessel staples.

Postoperative

Hemorrhage is the most serious immediate complication and typically originates from the short gastric or splenic vessels. Bleeding from either site can be profuse and potentially catastrophic. Thus, the initial 12 to 24 postoperative hours require vigilance (Magtibay, 2006).

The most common postoperative complication is left lower lobe lung atelectasis. This typically will resolve with ambulation, pulmonary therapy, and time. Development of a postoperative intra-abdominal abscess usually results from inadvertent injury to the stomach, splenic flexure, or distal pancreas. Excessive pancreatic manipulation or laceration may lead to pancreatitis or leaking. If a drain has been placed, fluid may be sent to the laboratory if any of these complications are suspected.

Patients undergoing splenectomy will be at lifelong risk for episodes of overwhelming sepsis. Accordingly, the pneumococcal vaccinate should be administered routinely postoperatively (see Table 1-1). In addition, patients should be instructed to seek

immediate medical attention for fevers that may progress rapidly to serious illness.

43-14 DIAPHRAGMATIC SURGERY

Patients with advanced ovarian cancer often will have tumor implants or confluent plaques involving the diaphragm. The right hemidiaphragm is affected most frequently. Implants typically are superficial, but invasive disease can extend through the peritoneum to the underlying muscle. Accordingly, gynecologic oncologists should be prepared to perform diaphragmatic ablation, stripping, (peritonectomy), or full-thickness resection. These surgical procedures increase the rate of optimal tumor debulking and correlate with improved survival (Aletti, 2006a).

Preoperative

PATIENT EVALUATION

Imaging studies may suggest diaphragmatic nodularity, but the extent is difficult to ascertain until exploration in the operating room.

CONSENT

Patients with presumed advanced ovarian cancer should be informed of the possible need for extensive upper abdominal surgery to achieve optimal cytoreduction. Pulmonary complications are most common after diaphragmatic surgical techniques and include atelectasis, empyema, subphrenic abscess, pleural effusions, and pneumothorax (Cliby, 2004).

Intraoperative

INSTRUMENTS

It is generally advisable to have a cavitational ultrasonic surgical aspiration (CUSA) system and/or argon beam coagulator (ABC) available for ovarian cancer debulking procedures because one or both may be useful in eradicating diaphragmatic disease. These tools are discussed further in Chapter 40, Electrosurgery.

Surgical Steps

1. **Anesthesia and Patient Positioning.** As with other major intra-abdominal surgeries, diaphragmatic surgery requires general anesthesia. The patient is positioned supine, the abdomen is surgically prepared to accommodate an incision to the sternum, and a Foley catheter is inserted.

2. **Abdominal Entry.** Diaphragmatic surgery requires a vertical midline incision that has been extended to the sternum, passing to the right side of xyphoid, for maximum exposure. Following abdominal entry, the surgeon should assess the entire abdomen and pelvis carefully to confirm the ability to resect all gross disease. Ideally, diaphragmatic surgery is performed only if optimal tumor debulking can be achieved.

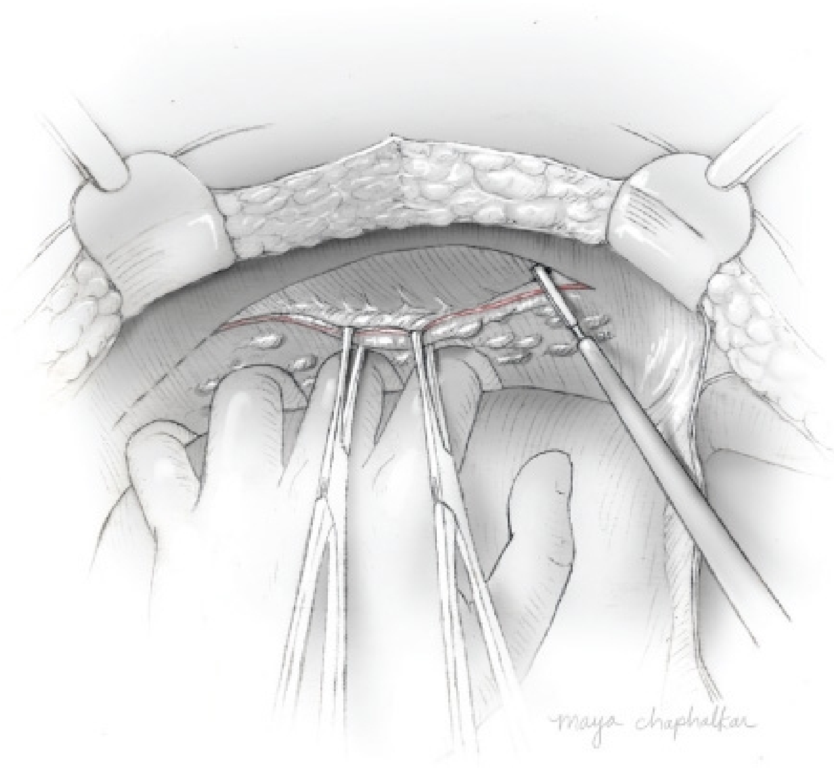
3. **Diaphragmatic Ablation.** A few scattered, small tumor implants on the surface of the right or left hemidiaphragm usually can be ablated easily with the CUSA or ABC. This simple technique may be all that is required.

4. **Diaphragmatic Stripping.** Confluent plaques of tumor or extensive implants indicate the need for resection of the peritoneum. The right side of the anterior rib cage is retracted sharply upward. The liver is retracted manually downward and medially to aid division of the falciform ligament with an electrosurgical blade, ligate-divide-staple (LDS) device, and/or clamps and delayed-absorbable suture ligation. This maneuver significantly mobilizes the liver and allows it to be held medially away from the diaphragm.

   Allis clamps are used to grasp the peritoneum above the tumor plaque and place it on tension. The peritoneal incision is created transversely with an electrosurgical blade, and a plane is developed with blunt dissection to separate the peritoneum from the underlying muscle fibers of the diaphragm. The free peritoneal edge is placed on tension with Allis clamps to maintain traction. The incision then is extended medially and laterally to encompass the implants (Fig. 43-14.1). The specimen eventually becomes large enough to grasp with a left hand to aid stripping of the peritoneum off the diaphragm. Electrosurgical blade dissection proceeds dorsally until all implants are contained within the peritoneal specimen. At this

point, it can be detached.

FIGURE 43-14.1



Source: Schorge JO, Schaffer JI, Halvorson LM, Hoffman BL, Bradshaw KD, Cunningham FG: *Williams Gynecology*: http://www.accessmedicine.com

Diaphragm stripping.

5. **Diaphragmatic Resection.** Occasionally, tumor has penetrated through the peritoneum, and a plane cannot be developed to strip the diaphragm. In these circumstances, full-thickness resection is required. A self-retaining retractor is placed, and the liver is mobilized. A transverse peritoneal incision is made above the tumor plaque, and at this point, the inadequacy of stripping is determined.

   The ventilator is turned off temporarily to avoid lung parenchymal injury, and an electrosurgical blade is used to cut through the diaphragmatic muscle into the pleural cavity above the tumor. Ventilation then may be resumed while Allis clamps are placed to retract the specimen into the peritoneal cavity. Both pleural and peritoneal surfaces should be visible to aid complete resection of the disease. Primary mass closure of the diaphragmatic defect then is performed with a running stitch using delayed-absorbable suture or interrupted stitches of silk suture.

   To evacuate the pneumothorax, a red rubber catheter is placed through the defect into the pleural space prior to securing the final knot. The ventilator is turned off at the end of inspiration to maximally inflate the lungs while the catheter is placed on suction. The catheter is removed concomitantly with tying the knot, and mechanical ventilation is resumed. Grafts typically are not needed, even for large defects (Silver, 2004).

6. **Final Steps.** The patient should be placed in the Trendelenburg position at completion of stripping or resection to check the

integrity of the diaphragmatic closure. The upper abdomen is filled with saline and observed for air leaks as the patient is ventilated. The presence of air bubbles indicates the need to reintroduce the red rubber catheter through the hole, resuture the defect, and retest the closure. Chest tubes are not required routinely.

Postoperative

Atelectasis is common with any diaphragmatic surgery. In addition, patients having full-thickness diaphragmatic resection are more likely to require postoperative ventilation and should be monitored carefully with chest radiographs for evidence of a pneumo- or hemothorax. These are generally manageable with chest tube drainage, lung re-expansion, and other supportive care measures.

43-15 COLOSTOMY

A colostomy creates a surgical anastomosis between created openings in the colon and anterior abdominal wall to divert bowel contents into an external collection bag. Colostomies serve several purposes and may be used to: (1) protect distal bowel repair from disruption or contamination by feces, (2) decompress an obstructed colon, and (3) evacuate feces if the distal colon or rectum is excised. In gynecologic oncology, there are innumerable specific indications for performing a colostomy. Some of the more common reasons include rectovaginal fistula, severe radiation proctosigmoiditis, bowel perforation, and rectosigmoid resection in which anastomosis is not feasible.

A colostomy may be temporary or permanent, and its duration is dictated by clinical circumstances. For instance, recurrent end-stage cervical cancer with obstruction may warrant a permanent colostomy. In contrast, only temporary diversion is needed to allow healing of an intraoperative bowel injury that occurred during benign gynecologic surgery.

In addition, the location of the stoma and the decision to perform an end or loop colostomy are also clinically based. A loop colostomy is constructed by creating an opening in a loop of colon and bringing both ends through the stoma. Alternatively, an end-colostomy stoma contains only the proximal end of the transected colon. The distal end is stapled and left intra-abdominally.

Regardless of the circumstances, the same surgical principles apply during colostomy: adequate bowel mobilization, sufficient blood supply, and a tension-free tunnel through the abdominal wall without bowel constriction. Strict attention to these seemingly straightforward steps will ensure the best possible outcome.

Preoperative

PATIENT EVALUATION

The colostomy site ideally is marked preoperatively by an enterostomal therapist to ensure that the postoperative stoma will be located in an easily accessible area when sitting and standing.

CONSENT

Concerns regarding postoperative quality-of-life changes are common with this procedure, and a surgeon should carefully describe a colostomy's medical purpose and its expected temporary or permanent duration. Many times, postoperative results are preferable to a patient's current symptoms and quality of life.

Perioperative complications may include fecal leakage into the abdomen or retraction of the stoma. Long-term complications involve parastomal hernia, stricture, and the potential need for surgical revision.

PATIENT PREPARATION

To minimize fecal contamination during bowel incision, aggressive bowel preparation such as with a polyethylene glycol with electrolyte solution (GoLYTELY). This is performed the day prior to surgery unless contraindicated, such as with bowel obstruction or perforation. Additionally, broad-spectrum antibiotics are given perioperatively because of possibility of stool contamination.

Intraoperative

Surgical Steps

1. **Anesthesia and Patient Positioning.** Colostomy is performed under general anesthesia with the patient positioned supine. Prior to surgery, the abdomen is surgically prepared, and a Foley catheter is inserted.

2. **Abdominal Entry and Exploration.** Colostomy generally requires a midline vertical incision for adequate exposure. The colon is elevated to ensure that it will reach the selected stoma site without tension. Dissection and adhesiolysis are performed as necessary to mobilize the bowel to obtain sufficient length before creating the abdominal wall stoma opening. If bowel fails to reach the selected site without tension despite adhesiolysis, then the stoma site is moved to accommodate bowel length.

3. **End Colostomy.** This type of diversion is used commonly for rectovaginal fistulas and severe proctosigmoiditis after radiation. Ideally, a more distal colon site is used because bowel content becomes progressively more solid and less voluminous as it moves from the cecum to the rectum. Moreover, if performing an end sigmoid colostomy, the distal bowel simply may be stapled closed and left in the pelvis (Hartmann pouch). In contrast, a more proximal end colostomy will require that the distal bowel also be brought to the abdominal wall and opened to serve as a "mucus fistula" to prevent a closed-loop obstruction and subsequent colonic perforation.

   The stoma site for a sigmoid colostomy is selected based on an imaginary line drawn from the umbilicus to the left-sided anterosuperior iliac spine. The stoma is typically place at an approximate midpoint along this line. A Kocher clamp is used to elevate the skin, and an electrosurgical blade, set to a cutting mode, is used to remove a 3-cm circle of skin. The fascia is exposed by blunt dissection. In obese patients, a cone of subcutaneous fat may need to be removed to prevent bowel constriction. A cruciate incision is made on the anterior sheath. The fibers of the rectus abdominis muscle are separated bluntly, and another cruciate incision is cut on the posterior sheath. The opening is expanded bluntly to accommodate two to three fingers.

   After the colon is divided, the proximal bowel should be mobilized by incising the peritoneum toward the splenic flexure along the white line of Toldt. A Babcock clamp then is placed through the skin opening to grasp the stapled end of the bowel and lift it through the abdominal opening (Fig. 43-15.1). The bowel should appear pink, and its mesentery must not be twisted. The primary vertical abdominal incision then is closed.

   The stoma is "matured" by first tilting the table to the left to avert bowel spillage. The staple line is then excised. Circumferential interrupted 3-0 and 4-0 delayed-absorbable sutures are placed through the bowel mucosa and skin dermis (Fig. 43-15.2). The ostomy bag appliance then may be attached.

Source: Schorge JO, Schaffer JI, Halvorson LM, Hoffman BL, Bradshaw KD, Cunningham FG: *Williams Gynecology*: http://www.accessmedicine.com

End-sigmoid colostomy: bowel mucosa sutured to skin.

4. **Loop Colostomy.** The usual indications for this type of procedure include protection of a distal anastomosis, relief of colonic obstruction, and treatment of colonic perforation. Accordingly, loop colostomy can be performed at any site along the colon where indicated. A loop colostomy in general is intended to be a temporary or palliative procedure. It is easier to take down, often simpler to perform, and does not necessarily require designation of loops as distal or proximal. However, fecal matter eventually will pass through to the distal segment, and as a result, this type of colostomy is not a permanent solution to a fistula or proctosigmoiditis.

   A transverse loop colostomy is performed in the left upper quadrant by making a 5-cm transverse incision over the rectus abdominis muscle midway between the costal margin and the umbilicus. The anterior and posterior fasciae, rectus abdominis muscle, and peritoneum are opened longitudinally by sharp and blunt dissection. The omentum is separated from the underlying transverse colon, and a 1/4 -in Penrose drain is placed through the mesocolon for traction. The bowel loop then is brought through the incision (Fig. 43-15.3). A Hollister bridge or similar device is passed through the mesenterotomy in place of the Penrose drain, and the incision is closed around the bowel loop without constricting it. The bowel is then "matured" by opening the antimesenteric half of the bowel along the tenia with an electrosurgical blade and leaving a 1-cm margin on each end (Fig. 43-15.4). The colostomy edges are sutured to the skin with interrupted stitches of 3-0 delayed-absorbable suture.

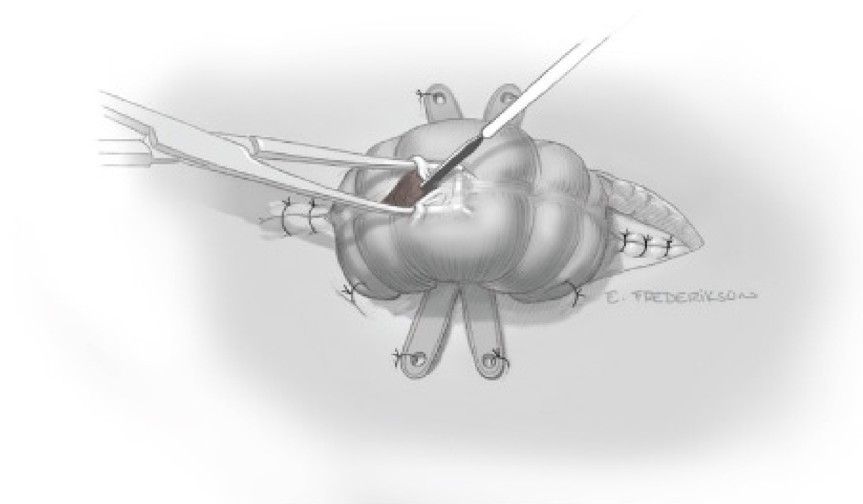
Transverse loop colostomy: elevation of bowel segment.

FIGURE 43-15.4



Transverse loop colostomy: opening of the bowel.

5. **Final Steps.** The stoma should be inspected carefully, and ideally, a stoma is pink and comfortably positioned. A dusky color may indicate bowel ischemia, which can lead to sloughing, necrosis, and retraction. Tension on the bowel may be improved with additional mobilization. Constriction of a loop colostomy within the abdominal wall opening can be improved by broadening the fascial incision or removing additional subcutaneous fat. On occasion, the tip of an end colostomy may need to be transected further distally to reach a viable bowel segment. All these steps are cumbersome but much easier to perform during the operation than postoperatively after complications have become obvious.

Postoperative

Morbidity is comparable for end and loop colostomies (Segreti, 1996b). Complications may be immediate or not evident for several months. Common complications specific to a colostomy may include wound infection, necrosis, bowel obstruction, hematoma, retraction, fistula, fecal leakage, sepsis, stricture, and parastomal herniation (Hoffman, 1992). Many of these complications are manageable with supportive care and local measures. Dramatic symptoms are infrequent but may require operative revision. Careful attention during initial surgery will prevent most of these morbidities.

43-16 LARGE BOWEL RESECTION

Partial colectomy is performed most often as part of cytoreductive surgery for ovarian cancer. Other indications include radiation injury and colonic fistulas. Surgical principles are similar, whether a bowel segment to be removed is from the ascending, transverse, or descending colon. Rectosigmoid (low anterior) resection is somewhat more complex and is reviewed in Section 43-19, Low Anterior Resection.

Ideally, during colectomy, a surgeon will achieve meticulous hemostasis, remove the smallest required length of colon, avoid fecal spill, and exclude proximal or distal intestinal obstruction. In addition, bowel must be sufficiently mobilized to create a tension-free anastomosis that is watertight, large caliber, and supported by adequate blood supply.

A general familiarity with colonic blood supply is important for partial colectomy. The ascending and transverse colons are supplied by the superior mesenteric artery via the middle colic, right colic, and ileocolic branches. The descending and sigmoid colons are supplied by the left colic and sigmoid branches of the inferior mesenteric artery. As a result, these vessels form an effective anastomotic vascular network that allows large bowel resection at virtually any segment of the colon.

Preoperative

PATIENT EVALUATION

The need for partial colectomy during ovarian cancer cytoreductive surgery usually is decided intraoperatively and is based on clinical circumstances. For example, although a preoperative computed tomographic (CT) scan may suggest tumor at multiple sites near the colon, these lesions often are superficial and may be removed without colectomy. Typically, the need for colectomy is more obvious preoperatively for those with radiation damage or fistulas, but the extent of the resection still generally will be unclear until the operation is underway.

CONSENT

Patients should be fully informed of the potential for colostomy, for anastomotic leak, and for abscess formation. A postoperative ileus also should be anticipated.

PATIENT PREPARATION

To minimize fecal contamination during bowel incision, aggressive bowel preparation such as with a polyethylene glycol with electrolyte solution (GoLYTELY) is performed the day prior to surgery unless contraindicated, such as with bowel obstruction or perforation. However, if a bowel obstruction is present, then cleansing the distal colon with enemas is a secondary option. The patient also should be marked for a colostomy if this is possibility. Moreover, if a complicated resection or prolonged recovery is anticipated, total parental nutrition (TPN) administration should be considered. Antibiotic prophylaxis may be initiated prior to creating the abdominal incision.

Intraoperative

INSTRUMENTS

To prepare for complicated resections, a surgeon should have access to all types and sizes of bowel staplers, which include end-to-end anastomosis (EEA), gastrointestinal anastomosis (GIA), and transverse anastomosis (TA) staplers. Additionally, a ligate-divide-staple (LDS) device may be used for vessel ligation.

Surgical Steps

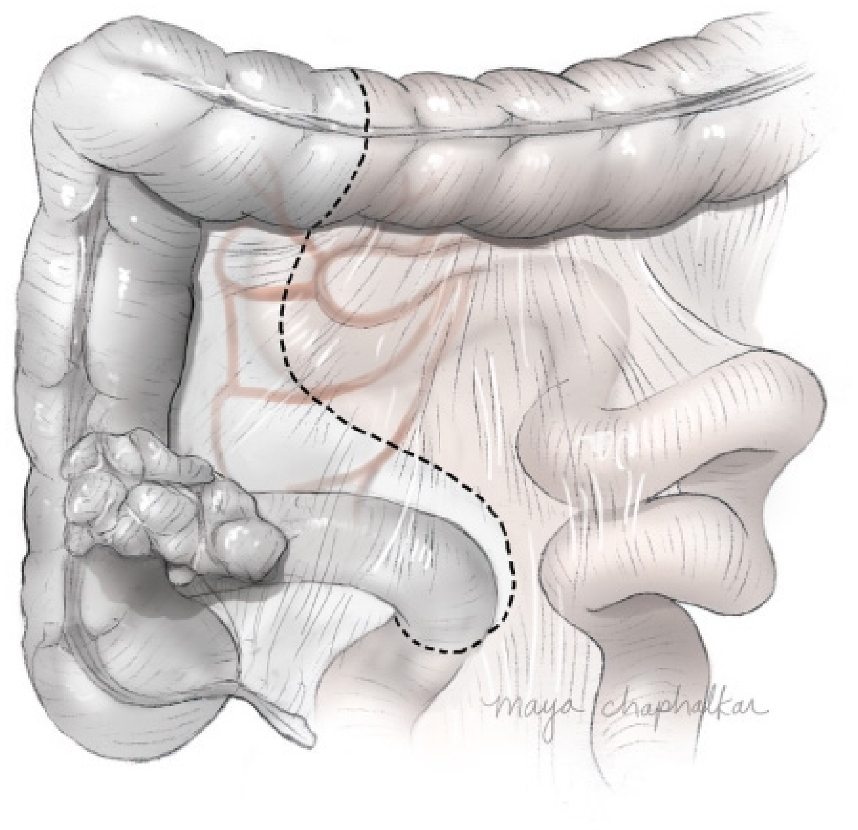
1. **Anesthesia and Patient Positioning.** Rectovaginal examination under anesthesia is mandatory before positioning any patient for abdominal gynecologic cancer surgery. A palpable mass with compression of the rectum or rectovaginal septum indicates the need for dorsal lithotomy with legs comfortably positioned in Allen stirrups to prepare for possible low anterior resection and anastomosis (see Section 43-19, Low Anterior Resection). Supine positioning is otherwise appropriate. Sterile preparation of the abdomen, perineum, and vagina is completed, and a Foley catheter is placed.

2. **Abdominal Entry.** A midline vertical incision is preferable if partial colectomy is anticipated to provide access to the entire abdomen. Required dissection, adhesiolysis, or other unanticipated findings may render transverse incision exposure inadequate.

3. **Exploration.** The surgeon should explore the entire abdomen first to lyse adhesions, to "run" the bowel and evaluate its appearance from duodenum to rectum, to exclude other potential sites of obstruction, and to determine the extent of the bowel resection. Blood supply at the splenic flexure, hepatic flexure, and ileocecal valve can be tenuous. As a result, resection boundaries should lie beyond these areas if possible. For example, in Fig. 43-16.1, because of the limited blood supply at the hepatic flexure, the proximal line of transection includes several centimeters of transverse colon. Similarly, the distal line of transection includes 8 to 10 cm of the terminal ileum because the ileocecal artery is sacrificed.

   A window is made in the mesocolon proximal and distal to the lesion. A 1/4 -in Penrose drain is pulled through each locations' opening to provide traction.

FIGURE 43-16.1



Source: Schorge JO, Schaffer JI, Halvorson LM, Hoffman BL, Bradshaw KD, Cunningham FG: *Williams Gynecology*: http://www.accessmedicine.com

Area of resection is shown to encompass the tumor.

4. **Mobilization of the Colon.** The bowel is next mobilized. This is performed by incising peritoneum along the white line of Toldt and/or the hepatic or splenic flexuresâ€"depending on the resection site. The left or right retroperitoneal space is entered beyond the distal Penrose drain by creating an opening with an electrosurgical blade just lateral to the colon. This space is expanded bluntly, and electrosurgical dissection is guided cephalad past the proximal Penrose drain while providing countertraction on the colon. The bowel segment may be mobilized bluntly medially as necessary. Omentectomy may be required for resections involving the transverse colon (see Section 43-12, Omentectomy).

5. **Resection.** A GIA stapler is inserted to replace one Penrose drain, is positioned around the entire colon diameter, and is fired. A second stapling and transection then are repeated at the other site. The bowel segment then may be detached from the underlying mesentery using an LDS device or individual clamps and delayed-absorbable suture ligation. During this process, as much of the mesentery as possible should be preserved. The specimen then is removed.

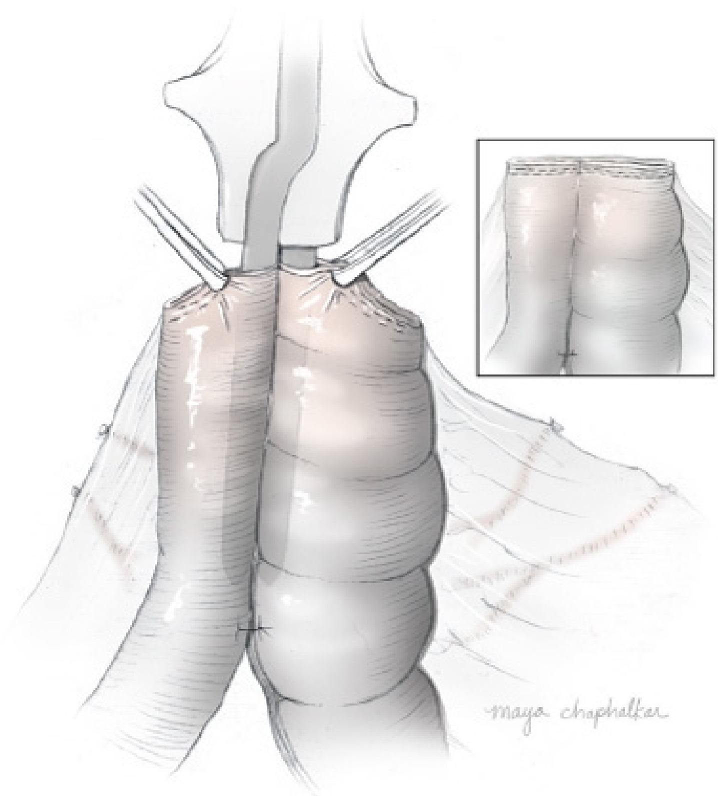
6. **Side-to-Side Anastomosis.** The remaining proximal and distal bowel ends are held against each other to estimate their position following anastomosis. Typically, additional mobilization of the bowel by incising adhesions and peritoneum is required using a combination of electrosurgical blade and blunt dissection. The two segments must comfortably approximate antimesenteric borders without tension. The proximal and distal stapled bowel ends are cleared of fatty tissue to create an anastomosis with maximal mucosa-to-mucosa contact. To accomplish this, the proximal staple line is elevated with two Allis clamps at its lateral edges. Debakey forceps place surrounding fatty tissue on traction, and an electrosurgical blade is used to

dissect this away from the bowel serosa. The dissection then is performed on the distal segment in similar fashion.

The staple lines are excised with scissors, and the bowel is held vertically to prevent fecal spill. One fork of the GIA stapler then is inserted as deeply as possible into one of the bowel lumens (Fig. 43-16.2). The bowel segments are evenly positioning, and the device is fired along the antimesenteric surfaces and removed. This stapler places two staggered rows of titanium staples and simultaneously transects tissue between these rows.

The bowel interior should be examined for bleeding sites, which may be coagulated electrosurgically. The remaining opening then may be stapled across with a TA stapler (see Fig. 43-18.3). Residual bowel tissue above the TA staple line is excised. The mesenteric defect is re-approximated with interrupted or running delayed-absorbable suture to prevent an internal hernia.

FIGURE 43-16.2



Source: Schorge JO, Schaffer JI, Halvorson LM, Hoffman BL, Bradshaw KD, Cunningham FG: *Williams Gynecology*: http://www.accessmedicine.com

GIA stapler connects a side-to-side anastomosis of the antimesenteric surfaces of the ileum and transverse colon. **Inset:** TA stapler line closes the distal end of the anastomosis.

7. **Final Steps.** The abdomen is irrigated with copious warmed saline at the conclusion of any bowel resection, especially if feces have spilled during the procedure. Drains are not required routinely and may impair healing.

Postoperative

Morbidity after large bowel resection is increased significantly by a variety of factors but especially by pre-existing obstruction,

malignancy, and sepsis. Anastomotic leaks are the most specific complication and typically present as an abscess, a fistula, or as peritonitis within days or weeks of surgery. Some localized leaks can be managed with initiation of total parenteral nutrition (TPN), CT-guided drainage, antibiotic administration, and bowel rest. However, urgent reoperation is indicated for nonlocalized intraperitoneal perforation and its resulting peritonitis. This usually will require colostomy (Hoskins, 1987).

Pelvic abscesses also may result from intraoperative fecal spillage or hematoma superinfection. Usually these will resolve with CT-guided drainage and antibiotics. Gastrointestinal hemorrhage should be rare with stapled procedures. In addition, symptomatic anastomotic strictures are infrequent and often present as colonic obstruction. Some strictures can be managed with endoscopic stents, but often they require re-operation. Small or large bowel obstructions also may result from postoperative adhesions or tumor progression. Lastly, a prolonged ileus can develop and be very slow to resolve. Most of these complications will depend primarily on the patient's underlying nutrition and the clinical circumstances prompting the primary surgery.

43-17 ILEOSTOMY

Relatively few patients will require ileostomy for management of a gynecologic malignancy. For those who do, loop ileostomy usually is a temporary procedure that is performed to protect a distal anastomosis (Nunoo-Mensah, 2004). In addition, diversion of a colonic fistula or palliation of a large bowel obstruction may be other indications (Tsai, 2006). On occasion, ovarian cancer will involve the entire colon, requiring colectomy with a permanent end ileostomy and formation of a Hartmann pouch (Weber, 1994).

Preoperative

PATIENT EVALUATION

Stoma placement is particularly important for an ileostomy because the effluent will be more corrosive than that of a colostomy. The stoma site is selected based on an imaginary line drawn from the umbilicus to the left-sided anterosuperior iliac spine. The stoma is typically place at an approximate midpoint along this line. Ideally, the site should be marked by an enterostomal therapist preoperatively.

CONSENT

In general, many of the complications of this procedure mirror those of colostomy: retraction, stricture, obstruction, and herniation. Patients should be informed that temporary loop ileostomies can be taken down later without a laparotomy.

PATIENT PREPARATION

Bowel preparation is preferred whenever there is a potential for bowel resection. However, ileostomy can be performed without an increased risk of infection without preoperative bowel cleansing.

Intraoperative

Surgical Steps

1. **Anesthesia and Patient Positioning.** Ileostomy is performed under general anesthesia. Patients generally are supine, but dorsal lithotomy or other positioning with access to the abdominal wall is acceptable.

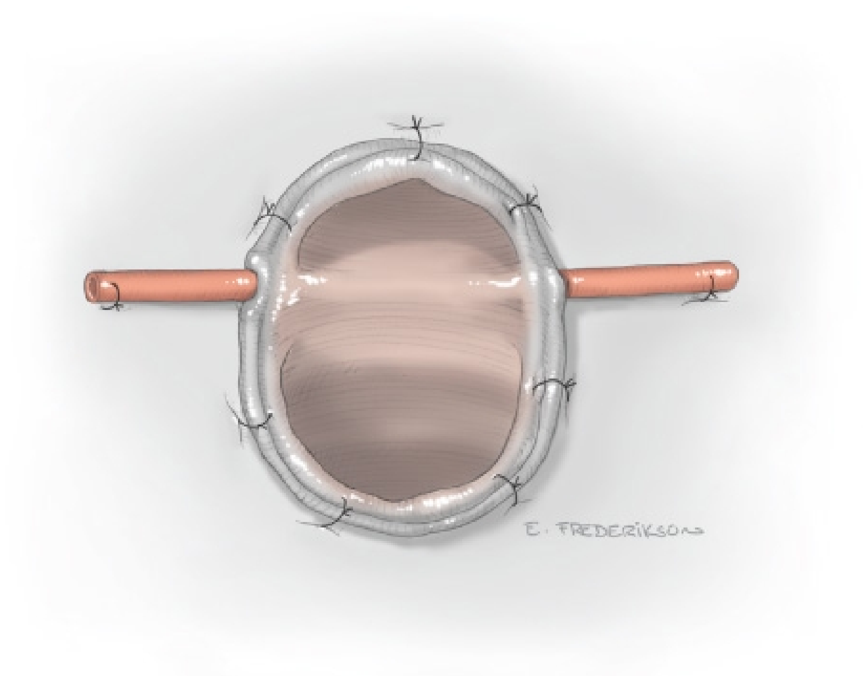
2. **Abdominal Entry.** A midline vertical incision is preferable for most situations in which an ileostomy is considered.

3. **Exploration.** After abdominal entry, the surgeon should first explore the abdomen, lyse adhesions, "run" the bowel length to identify obstructive sites, and determine the need for ileostomy. An ileum loop is selected that will reach several centimeters above the skin. Additionally, to reduce the effluent volume, the selected loop should be located as distally along the bowel length as possible. On occasion, tethering of small bowel by carcinomatosis or radiation injury will significantly reduce mobility and require a more proximal diversion.

4. **Loop Ileostomy.** A 1/4 -in Penrose drain is placed through a mesenterotomy at the selected loop's apex. The loop then can be approximated to the stoma site, which is created to accommodate two fingers, as described for an ileal conduit (see Section 43-6, Incontinent Urinary Conduit, Step 6). The loop is pulled through the abdominal wall opening so that several

centimeters protrude above the skin surface. The Penrose drain is removed and replaced with either the cut end of a red rubber catheter or other device that can be sewn to the skin to elevate the loop (Fig. 43-17.1). The loop should be tension-free and patent. Its proximal end is positioned lower to reduce fecal flow into the distal bowel. The abdominal wall then is closed around the stoma. The ileostomy is "matured" by longitudinally incising the bowel loop and everting its walls with Allis clamps. Circumferential interrupted stitches of 3-0 and 4-0 delayed-absorbable sutures are placed through the dermis and bowel mucosa. An ostomy bag then may be applied.

FIGURE 43-17.1



Source: Schorge JO, Schaffer JI, Halvorson LM, Hoffman BL, Bradshaw KD, Cunningham FG: *Williams Gynecology*: http://www.accessmedicine.com

Ileal loop has been pulled through the abdominal wall and opened with cautery.

Postoperative

The stoma should be examined carefully postoperatively for its appearance and function. The supporting rod may be removed in 1 to 2 weeks but potentially earlier if the stoma becomes dusky or the loops seem constricted or are obstructed.

Ileostomy may be associated with significant postoperative complications. High-output effluent also may result in electrolyte abnormalities that are difficult to correct. In addition, approximately 10 percent of patients will require early re-operation for small bowel obstruction or intra-abdominal abscess (Hallbook, 2002). Specifically, if loop ileostomy is indicated to protect a low anterior anastomosis, it is more commonly associated with bowel obstruction and ileus than loop colostomy (Law, 2002). Long-term complications such as a peristomal hernia and retraction are also possible.

43-18 SMALL BOWEL RESECTION

There are numerous indications for small bowel resection in gynecologic oncology, including obstruction, involvement with cancer, perforation, intraoperative injury, fistulas, and radiation damage. Unlike the large bowel, where greater attention is required to ensure an adequate blood supply to the anastomotic site, the small intestine has a consistent cascade of vessels that all arise from the superior mesenteric artery. However, unique situations such as radiation damage, obstructive dilatation, and edema can

compromise this vasculature dramatically. In these situations, meticulous dissection is especially crucial to prevent inadvertent removal of the bowel serosa, enterotomy, and bowel damage that will impair anastomotic healing. In general, surgical principles with this procedure are much the same as those for large bowel resection (see Section 43-16, Large Bowel Resection).

Preoperative

PATIENT EVALUATION

Small bowel obstructions (SBO) that do not resolve with nasogastric suction decompression and bowel rest may result from postoperative adhesions or tumor progression. Patients with recurrent gynecologic malignancy, particularly those with ovarian cancer, should be evaluated with an upper gastrointestinal series and small bowel follow-through radiographic studies preoperatively. With these, numerous sites of obstruction may be identified that would indicate a woman with end-stage disease who might be better served by placement of a palliative percutaneous draining gastrostomy tube. Patients with an SBO following pelvic radiation almost invariably have stenosis at the terminal ileum.

CONSENT

Depending on circumstances, patients should be counseled about the intraoperative decision-making process for performing an anastomosis, bypass, or ileostomy. Leaking and/or fistula formation are possible complications. Less common outcomes include re-obstruction, short bowel syndrome, and vitamin B_{12} deficiency.

PATIENT PREPARATION

Aggressive bowel preparation such as with a polyethylene glycol with electrolyte solution (GoLYTELY) performed the day prior to surgery is ideal but may be contraindicated in patients with obstruction. Antibiotic prophylaxis should be initiated. If a complex fistula is present or an extensive resection for radiation damage is anticipated, then total parental nutrition (TPN) may be advisable.

Intraoperative

The small intestine can be damaged easily by rough handling and extensive blunt dissectionâ€”particularly if it is edematous or previously radiated. Trauma should be kept to an absolute minimum to reduce spillage of intestinal contents and avoid postoperative sepsis.

INSTRUMENTS

The surgeon should have access to all types and sizes of bowel staplers, such as end-to-end anastomotic (EEA), gastrointestinal anastomotic (GIA), and transverse anastomotic (TA) staplers, to prepare for complicated resections.

Surgical Steps

1. **Anesthesia and Patient Positioning.** Small bowel resection is performed under general anesthesia. Patients are generally supine, but dorsal lithotomy or other positioning with access to the abdominal wall is acceptable.

2. **Abdominal Entry.** A midline vertical incision is preferable for most situations in which an small bowel resection is considered.

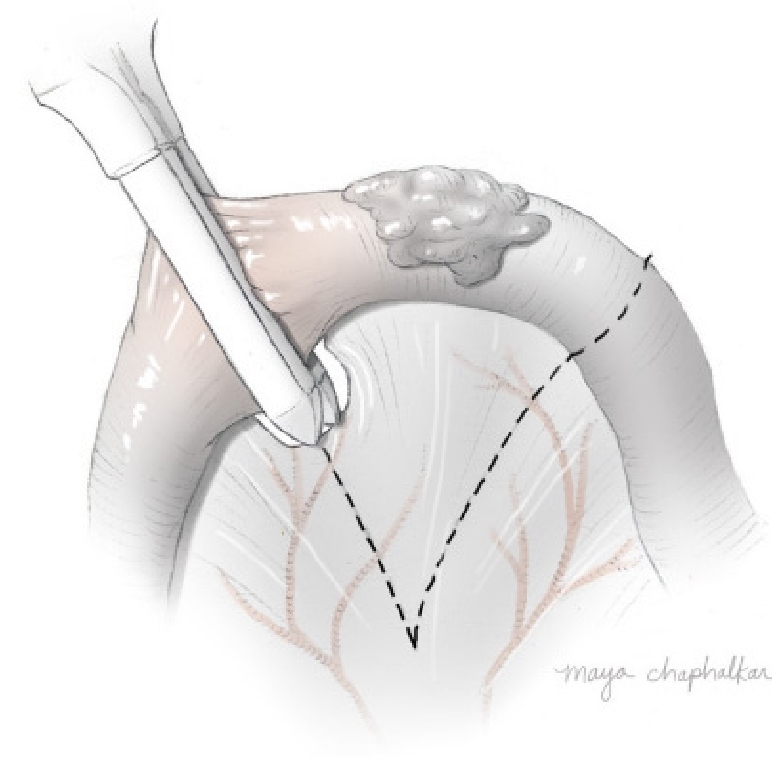
3. **Exploration.** The surgeon should explore the entire abdomen first to identify the obstruction. Infrequently, an adhesion may be located and lysed to relieve an obstruction and completely avoid small bowel resection. More often, an area is discovered that warrants removal. Additionally, the remainder of the bowel should be examined to exclude other obstructive sites.

   Peritoneum and adhesions attached to the involved portion of small bowel are transected to mobilize the bowel. Ideally, healthy-appearing serosa for anastomosis is identified both proximal and distal to the lesion while preserving a maximum amount of intestine.

4. **Dividing Small Bowel.** The bowel is brought through the incision. A 1/4 -inch Penrose drain is pulled through a mesenterotomy at the proximal and distal sites. A GIA stapler is inserted to replace the Penrose drain, fired, and repeated on the other site (Fig. 43-18.1). These staple lines minimize contamination of the abdomen with bowel contents.

A wedge of mesentery then is "scored" by superficially creating a V shape with an electrosurgical blade. The mesentery is divided by an LDS device and/or clamps and delayed-absorbable sutures ligatures. Hemostasis will be more difficult with edematous or inflamed tissue, and thus smaller pedicles should be divided. The bowel specimen is removed.

FIGURE 43-18.1



Source: Schorge JO, Schaffer JI, Halvorson LM, Hoffman BL, Bradshaw KD, Cunningham FG: *Williams Gynecology*: http://www.accessmedicine.com

Identifying the proximal and distal sites.

5. **Performing Side-to-Side Anastomosis.** The proximal and distal bowel segments are elevated with Allis clamps and matched along their antimesenteric borders. A single silk stay suture is placed through the antimesenteric border of each segment beyond the tip of where the GIA stapler fork will reach. The antimesenteric corner of each segment is excised just deeply enough to enter the lumen and sufficiently wide to permit passage of one GIA stapler fork. Massively distended bowel from an obstruction may be decompressed by inserting a pool suction tip into the proximal end.

   Allis clamps are replaced on the bowel at the edge of the each opening. These clamps and silk stay sutures assist insertion of one fork of the GIA stapler into each segment and aid bowel positioning (Fig. 43-18.2). The bowel is rotated to bring the antimesenteric borders together, Allis clamps are removed, and the GIA stapler is closed and fired.

   The remaining enterotomy is regrasped with three Allis clamps to approximate closure. The TA stapler is placed around the bowel beneath the Allis clamps and is closed (Fig. 43-18.3). The Allis clamps elevate the enterotomy and assist correct positioning of the TA stapler. The stapler is fired, excess tissue is trimmed sharply, and the stapler is opened and removed. The mesenteric defect may be closed next with running delayed-absorbable suture to prevent internal herniation.

Closing the enterotomy.

6. **Final Steps.** Copious irrigation with warmed saline should be performed at the conclusion of any bowel resection, but particularly if spillage is noted during the procedure. Drains are not required routinely and may impair healing. In general, placement of a nasogastric tube to decompress the stomach postoperatively until bowel function has resumed is prudent.

Postoperative

The underlying health of the patient, diagnosis, and indications for small bowel resection will dictate much of the potential postoperative morbidity. Common minor complications include wound infection and ileus. Fistula formation, anastomotic leakage, and obstruction are more serious problems that may require re-operation. Two specific complications are unique to extensive small bowel surgery.

First, short bowel syndrome may follow resection. With resection, more than half of the small intestine can be removed without impairing nutritional absorption as long as the remaining bowel is functional. Accordingly, this syndrome is more likely is to develop from extensive radiation damage than resection. Symptoms include diarrhea and dehydration. Maldigestion, malabsorption, nutritional deficiencies, and electrolyte imbalance are noted commonly. As a result, home parenteral nutrition may be required in some patients (King, 1993).

A second complication, vitamin B_{12} deficiency results from inadequate absorption and depletion of available stores. Vitamin B_{12} and bile salts are only absorbed in the distal 100 cm of the ileum. Malabsorption in this segment may result from radiotherapy or intestinal resection (Bandy, 1984). In these patients, long-term intramuscular vitamin B_{12} injections are required.

43-19 LOW ANTERIOR RESECTION

Rectosigmoid resection, also known as *low anterior resection,* is used mainly in gynecologic oncology to achieve optimal cytoreduction of primary or recurrent ovarian cancer (Mourton, 2005). This procedure is distinguished from other types of large bowel resections in that it requires mobilization of the rectum and transection of the rectum distally, below the peritoneal reflection. Following resection of the involved rectosigmoid segment, proximal and distal bowel ends usually are then reanastomosed.

Low anterior resection is the most common bowel operation for primary debulking (Hoffman, 2005). For example, en bloc pelvic resection combines low anterior resection with hysterectomy, bilateral salpingo-oophorectomy, and removal of surrounding peritoneum (see Section 43-11, En Bloc Pelvic Resection) (Clayton, 2002). In addition, total and posterior pelvic exenterations incorporate the principles of low anterior resection to remove centrally recurrent cervical cancer with widely negative soft tissue margins (see Sections 43-3, Total Pelvic Exenteration and 43-5, Posterior Pelvic Exenteration). Other less common indications for low anterior resection are radiation proctosigmoiditis and intestinal endometriosis (Urbach, 1998). Occasionally, additional large or small bowel resections will be performed concomitantly with low anterior resection (see Sections 43-16, Large Bowel Resection and Section 43-18, Small Bowel Resection) (Guidozzi, 1994).

Preoperative

PATIENT EVALUATION

Bowel symptoms may or may not be present in women with rectosigmoid involvement of ovarian cancer. However, the surgeon should have high suspicion if patients describe rectal bleeding or progressive constipation. A rectovaginal examination may help to predict the need for low anterior resection. Additionally, CT scanning may suggest rectosigmoid invasion of tumor. However, prior to surgery, prediction is difficult. Many ovarian cancers intraoperatively may be easily lifted away from the bowel and surface tumors may be removed without resection.

CONSENT

Patients should be prepared for the possibility of low anterior resection any time ovarian cytoreductive surgery is discussed. The survival benefit of achieving minimal residual disease warrants the risks of this procedure. However, low anterior resection extends operative time significantly, and hemorrhage may contribute to a need for blood transfusion (Tebes, 2006).

In general, progressively higher complication rates and poorer long-term bowel function follow more distal anastomoses that approach the anal verge. However, the operation is designed to encompass the tumor, and an end-sigmoid colostomy with Hartmann pouch is another, albeit less attractive, option for very low resections.

In general, a protective loop colostomy or ileostomy is not required, but patients should be counseled for this possibility (see Sections 43-15, Colostomy and 43-17, Ileostomy). Anastomotic leaks should develop in fewer than 5 percent of patients (Mourton, 2005).

PATIENT PREPARATION

To minimize fecal contamination during resection, bowel preparation such as with a polyethylene glycol with electrolyte solution (GoLYTELY) is mandatory prior to surgery. Antibiotic prophylaxis may be initiated in the operating room.

Intraoperative

INSTRUMENTS

All types and sizes of bowel staplers such as end-to-end anastomosis (EEA), gastrointestinal anastomosis (GIA), and transverse anastomosis (TA) staplers should be available. Additionally, a ligate-divide-staple (LDS) device may be used for vessel ligation.

Surgical Steps

1. **Anesthesia and Patient Positioning.** Low anterior resection typically requires general anesthesia. Rectovaginal examination under anesthesia is mandatory before positioning any patient for abdominal gynecologic cancer surgery. A palpable mass with compression of the rectum or rectovaginal septum warrants patient positioning in the dorsal lithotomy

position with the legs comfortably placed in Allen stirrups. This allows access to the rectum in patients requiring EEA stapler insertion for anastomosis. Alternatively, supine positioning may be appropriate if no mass is palpable by rectovaginal examination. In such cases, if a mass is located more proximally, low rectal anastomosis can be performed entirely within the pelvis.

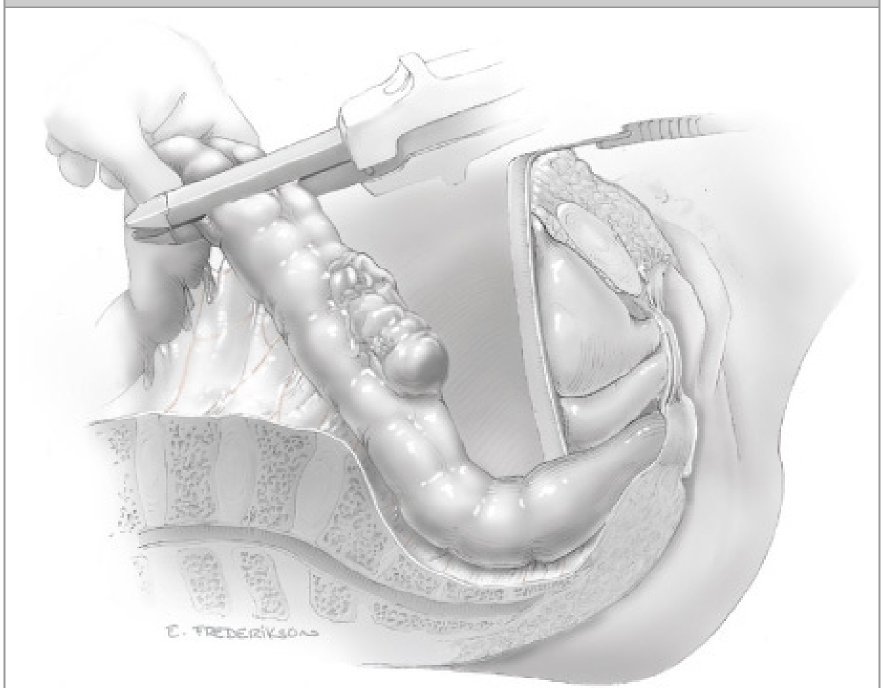
2. **Abdominal Entry.** A midline vertical incision provides generous operating space and upper abdominal access. This is preferable if low rectal anastomosis is anticipated because the descending colon may need to be mobilized around and beyond the splenic flexure. In contrast, transverse incisions often fail to provide sufficient exposure.

3. **Exploration.** The surgeon should explore the entire abdomen first to determine if disease is resectable. If not, then the procedure's benefit should be re-evaluated. On occasion, imminent bowel obstruction, infection, or other clinical circumstances may dictate resection regardless of residual tumor. The pelvis and rectosigmoid should be palpated to plan for the resection and determine whether en bloc pelvic resection or an exenterative procedure is indicated.

4. **Visualization.** The bowel is packed into the upper abdomen, and retractor blades are positioned to allow access to the deep pelvis and the entire rectosigmoid colon. Ureters are identified at the pelvic brim and held laterally on Penrose drains to expose the peritoneum and mesentery, which can be safely dissected next.

5. **Dividing the Proximal Sigmoid.** The sigmoid colon is held on traction proximal to the tumor and in the approximate area where it will be divided. The ureter is located, and a right-angle clamp is used to guide superficial electrosurgical blade dissection of the peritoneum and mesentery up to the bowel serosa. This is repeated on the other side. Blunt dissection then may be performed to define the entire circumference of the sigmoid. Epiploica and adjacent fatty tissue are held with Debakey forceps and dissected away with an electrosurgical blade from the proposed area of transection. The GIA stapler is placed across the sigmoid, fired, and removed (Fig. 43-19.1).

FIGURE 43-19.1



Source: Schorge JO, Schaffer JI, Halvorson LM, Hoffman BL, Bradshaw KD, Cunningham FG: *Williams Gynecology*: http://www.accessmedicine.com

Dividing the proximal end.

6. **Dividing the Mesentery.** The entire mesentery now may be divided to provide access to the avascular plane between the rectosigmoid and the sacrum (retrorectal space). Gentle blunt dissection is performed inferior to the divided sigmoid to better characterize the underlying fatty tissue and small vessels. A right-angle clamp is placed through sections of the mesentery, and an LDS device divides this tissue. Dissection is continued anteroposteriorly through approximately two-thirds of the mesentery. Typically, one or more pedicles will have a blood vessel that slips out and requires clamping with a right-angle clamp and ligation with delayed-absorbable suture.

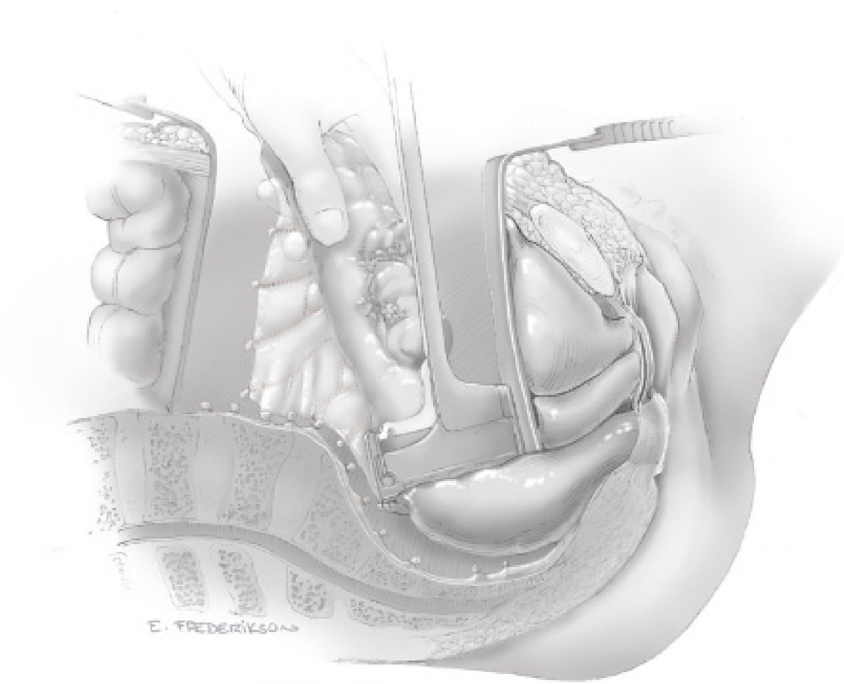
   Blunt dissection is performed in the pelvic midline to identify the large superior rectal vessels (branches of the inferior mesenteric artery [IMA]). This artery and vein are large and should be separately doubly clamped, cut, and ligated with delayed-absorbable suture. Dissection is continued to the other side of the pelvis until there is no tissue visible between the ureters. The common iliac artery bifurcation and sacrum should be entirely visible.

7. **Dividing the Rectum.** The proximal sigmoid and attached mesentery are repacked into the upper abdomen to improve pelvic exposure. The rectosigmoid is held superiorly, and blunt dissection is performed posteriorly in the retrorectal space to mobilize the distal bowel beyond the tumor to define the location of planned resection. The ureters are traced along the pelvic sidewall. Lateral blunt dissection is performed to further mobilize the rectosigmoid. Lateral mesenteric attachments are isolated and divided with an LDS device or grasped between Pean clamps, cut, and ligated. Self-retaining retractor blades may require repositioning as dissection proceeds more distally.

   The anterior bowel serosa generally is visible throughout its course beyond the peritoneal reflection and into the levator muscles. Lateral and posterior bowel margins are surrounded by fatty tissue, mesentery, and rectal pillars. The distal rectum beyond the tumor is grasped and rotated to aid exposure of these attachments. Alternating electrosurgical blade dissection, LDS division, and/or right-angle clamping and transection are used circumferentially until the rectal serosa is entirely visible.

   The rectosigmoid is held on traction, and the pelvis is re-examined to determine which size TA stapler is suitable and whether a roticulator will be required to fit into the space. A roticulator serves as a mobile joint for the stapler and, within a confined space, permits perpendicular positioning of the stapler across the rectum. The TA stapler then is inserted into the pelvis around the rectal segment. The ureters and any lateral tissue are pushed safely away, and the stapler is fired (Fig. 43-19.2). A knife blade is used to divide the proximal end of the rectum, and the low anterior resection specimen is removed. The TA stapler is opened and passed off the field. The pelvis is irrigated, and a laparotomy sponge is left in place to tamponade any surface oozing.

FIGURE 43-19.2

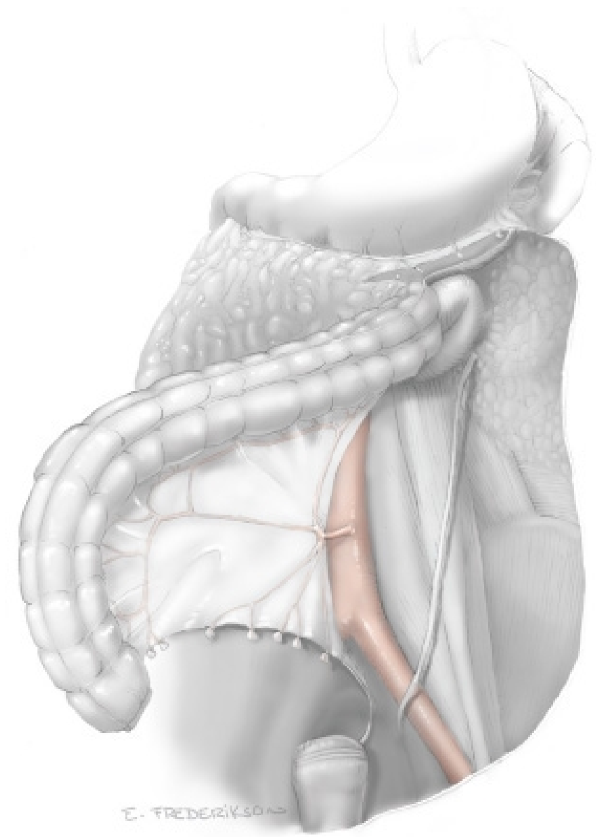


Source: Schorge JO, Schaffer JI, Halvorson LM, Hoffman BL, Bradshaw KD, Cunningham FG: *Williams Gynecology*: http://www.accessmedicine.com

Dividing the distal end.

8. **Mobilization.** The decision now is made to perform an anastomosis instead of an end-sigmoid colostomy (see Section 43-15, Colostomy). The upper abdominal retractors are removed, and the proximal sigmoid colon is mobilized by incising peritoneum along the white line of Toldt toward the splenic flexure. A combination of electrosurgical blade and blunt dissection typically is used. The proximal sigmoid colon is intermittently placed into the deep pelvis to assess the extent of further dissection needed to achieve a tension-free anastomosis. Ideally, the proximal sigmoid colon sits comfortably on top of the distal rectum. To achieve this, mobilization at times may encompass the splenic flexure (Fig. 43-19.3). Occasionally, the hepatic flexure may need to be mobilized also. Sufficient mobilization is critical to ensure a tension-free anastomosis.

FIGURE 43-19.3



Mobilizing the descending colon.

9. **Preparing the Anastomic Sites.** The proximal and distal stapled bowel ends now must be cleared of any fatty tissue or epiploica to allow sufficient mucosa-to-mucosa contact during anastomosis. The staple line of the proximal sigmoid is grasped with two Allis clamps at the lateral edges and elevated. Debakey forceps are used to place any surrounding fatty tissue on traction, and an electrosurgical blade is used to dissect these away from the bowel serosa. This can be particularly difficult in patients with prominent diverticulosis. A similar dissection also may be required on the distal rectal segment.

10. **Placing the Anvil.** The largest possible EEA circular stapler that will fit the bowel segments, typically 31- or 34-mm size, should be used. This provides a commodious anastomosis that will lessen the chances of symptomatic rectal stenosis. The proximal sigmoid colon again is held with Allis clamps, and scissors are used to remove the entire staple line. The Allis clamps are replaced to grasp the mucosa/serosa and hold open the proximal sigmoid. Sizing instruments may be used if necessary to decide which EEA instrument is best. The anvil is detached from the stapler, lubricated, and gentle inserted by rotating it into the proximal sigmoid. Its concave surface faces proximally, away from the anticipated anastomotic site (Fig. 43-19.4 Inset). Sequential stitches that pierce through bowel serosa, muscularis, and mucosa create a purse string around the anvil. These through-and-through stitches using 2-0 Prolene are placed 5 to 7 mm from the mucosal edge. The purse string begins and ends on the outside of the bowel serosa around the anvil spike and then is tied securely. Allis clamps are removed. Irrigation may be performed if bowel contents have spilled.

11. **Placing the Stapler.** The distal rectal stump is re-examined to ensure that all surrounding fatty tissue has been dissected

free. The surgical team then reviews the details of using an EEA instrument. The shaft is extended and spike attached. The shaft then is retracted into the instrument. The EEA is lubricated and gently inserted into the anus until the circular outline is visible and seen to be gently pressing on the rectal staple line. The wing nut is gently rotated and guided by the abdominal surgeon so that the spike tents the mucosa just posterior to the staple line. Gentle abdominal countertraction may be helpful as the spike pops through the entire bowel thickness. The shaft becomes visible, and the spike is removed with a Pean clamp.

12. **Stapling.** The abdominal surgeon lowers the proximal sigmoid to the distal rectum and connects the anvil with the EEA shaft. An audible click should be heard to confirm the placement. The tip of the EEA is held perfectly still while the wing nut is again rotated to retract the shaft back into the EEA until the handle indicator is in the correct position (Fig. 43-19.4). The safety is released, and the instrument is fired by squeezing and depressing the handles completely (incomplete squeezing can result in partial stapling). The wing nut then is turned to the specified position to release the staple line. The EEA with its attached anvil then is gently rotated and slowly removed from the rectum. The anastomosis should be visualized by the abdominal surgeon throughout the process. Distal retraction of the anastomosis or inability to remove the EEA suggests that the stapler was not completely fired. This situation may be salvaged by gently pulling the EEA through the anus and cutting inside the staple line to release the anastomosis. The anvil is removed from the EEA instrument and inspected to confirm that two completely intact circular "donuts" of rectal tissue are present.

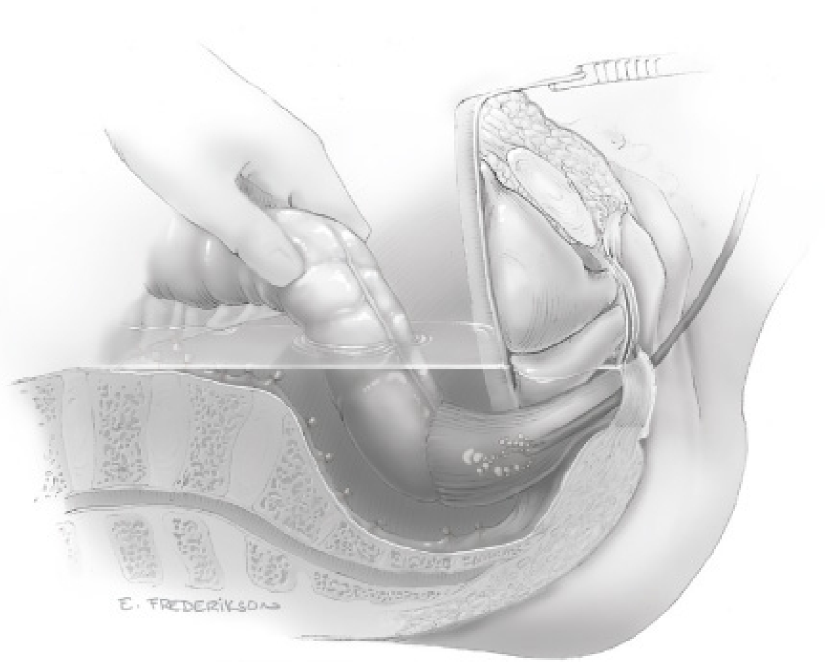
Performing the end-to-end anastomosis.

13. **Rectal Insufflation.** Warmed saline is irrigated into the pelvis. The integrity of the anastomosis now may be checked by gently inserting a proctoscope or red rubber catheter into the anus, but distal to the anastomosis, and insufflating air. The abdominal surgeon should gently palpate the sigmoid to make certain that air is entering the sigmoid proximal to the anastomotic site. No air bubbles should be visible when the connection is watertight (Fig. 43-19.5). The appearance of bubbles suggests a leak, but this should be double-checked for authenticity. Occasionally, air is being erroneously pumped into the vagina owing to incorrect placement. If there is any valid suspicion for a leak, the distal rectum should be divided again with the TA stapler and the anastomosis redone. Diverting colostomy also may be considered if the problem cannot be managed otherwise.

FIGURE 43-19.5



Source: Schorge JO, Schaffer JI, Halvorson LM, Hoffman BL, Bradshaw KD, Cunningham FG: *Williams Gynecology*: http://www.accessmedicine.com

Testing the anastomosis.

14. **Final Steps.** All pedicle sites should be rechecked for hemostasis and the pelvis irrigated. Nasogastric suction is not required routinely. In addition, suction drainage does not necessarily improve outcome or influence the severity of complications. (Merad, 1999).

Postoperative

The most common early postoperative complications are similar to those of other major abdominal operations and include fever, ileus, wound separation, and anemia requiring transfusion. Serious events such as bowel obstruction and fistula should develop infrequently (Gillette-Cloven, 2001). Long term, many patients will have a poor functional result, including fecal incontinence or chronic constipation (Rasmussen, 2003).

Low rectal anastomoses have much higher leak rates than intraperitoneal large bowel anastomoses. Occasionally, this complication can be managed successfully with percutaneous drainage and bowel rest. Otherwise, a diverting colostomy may be required. Risk factors for postoperative leakage include previous pelvic irradiation, diabetes mellitus, low preoperative serum albumin, surgical duration, and a low anastomosis (≤6 cm from the anal verge) (Matthiessen, 2004; Mirhashemi, 2000; Richardson, 2006). Other potential causes are technical missteps or inadequate bowel preparation. Suction drainage may prevent some leaks by removing blood, serum, and cellular dÃ©bris as a culture medium but also can impair healing if placed too close to the anastomotic site (Hirsch, 1997; Vignali, 1997).

43-20 INTESTINAL BYPASS

This bowel anastomotic procedure typically connects a section of the ileum to the ascending or transverse colon and thereby "bypasses" a portion of diseased bowel. Following anastomosis, the closed, bypassed small bowel segment remains.

There are relatively few indications for intestinal bypass in gynecologic oncology, and this procedure accounts for only approximately 5 percent of all bowel operations performed for these cancers (Barnhill, 1991). In all circumstances, removal of diseased bowel and end-to-end anastomosis are preferable (Hoskins, 1987). However, some patients will have unresectable tumor, dense adhesions, extensive radiation injury, or other factors that prohibit this. In these patients, a poor decision to perform an aggressive dissection can result in numerous enterotomies, hemorrhage, or other intraoperative catastrophies with major postoperative sequelae. Instead, an intestinal bypass can be performed quickly with minimal morbidity. Many times a bypass is selected because it is the easiest palliative maneuver for a terminally ill patient. The main purpose is to re-establish an adequate bowel communication to relieve an obstruction and regain the ability to take oral nourishment.

Preoperative

PATIENT EVALUATION

The intestinal tract should be evaluated carefully by an upper gastrointestinal (GI) radiologic series with small bowel follow-through and/or computed tomographic (CT) scanning. Invariably, radiation injuries are located at the terminal ileum, but there may be complex fistulas or multiple sites of obstruction to be addressed. In most circumstances in which a bypass is considered, the surgeon should anticipate limitations in exploring the abdomen adequately intraoperatively. Careful analysis of preoperative findings will help to ensure that bypass encompasses the entire lesion and does not leave a distal obstruction.

CONSENT

Patients usually have a miserable quality of life when bypass is considered, and the operation's main goal is to improve patient symptoms. The counseling process should emphasize that intraoperative judgment will dictate whether a small bowel resection, ileostomy, large bowel resection, colostomy, or bypass is indicated. Many risks are similar to those of other intestinal surgical procedures and include anastomotic leaks, obstruction, abscess formation, and fistula. Blind loop syndrome, discussed later, is one long-term complication that is characteristic to the bypass procedure.

PATIENT PREPARATION

To minimize fecal contamination during bowel incision, aggressive bowel preparation such as with a polyethylene glycol with electrolyte solution (GoLYTELY) is performed the day prior to surgery unless contraindicated, such as with bowel obstruction or perforation. Additionally, broad-spectrum antibiotics are given perioperatively because of the possibility of stool contamination. If a prolonged recovery is anticipated, total parenteral nutrition should be considered.

Intraoperative

INSTRUMENTS

To prepare for complicated resections, bowel staplers such as an end-to-end anastomosis (EEA), gastrointestinal anastomosis (GIA), and transverse anastomosis (TA) staplers should be available.

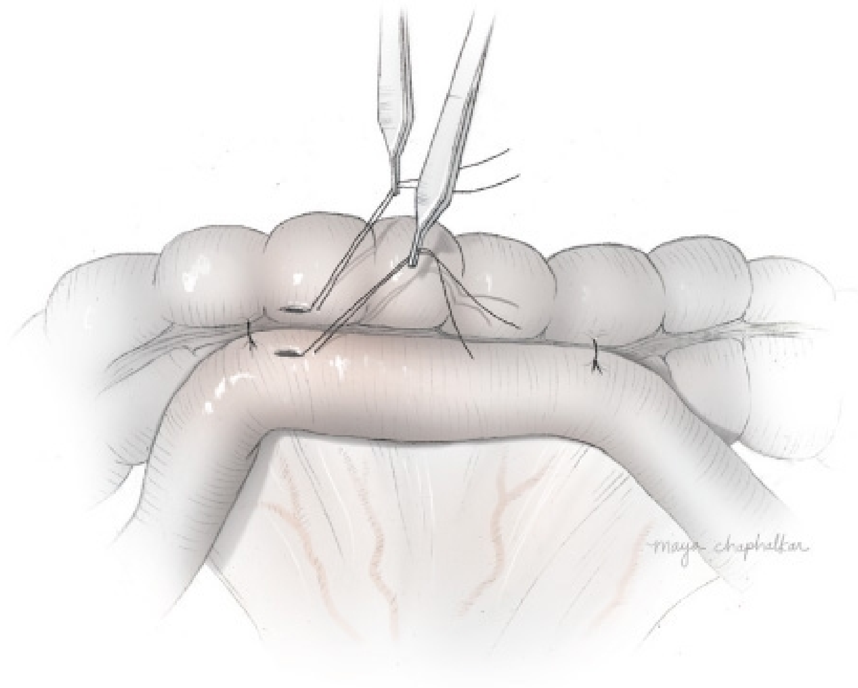
Surgical Steps

1. **Anesthesia and Patient Positioning.** Bypass is performed under general anesthesia with the patient positioned supine. Prior to surgery, the abdomen is surgically prepared, and a Foley catheter is inserted.

2. **Abdominal Entry and Exploration.** Intestinal bypass generally requires a midline vertical incision for adequate exposure. The surgeon should explore the entire abdomen first to identify bowel lesions. In addition, the remaining bowel should be examined to exclude other obstructive sites. Healthy-appearing bowel proximal and distal to the lesion is selected with the intent of preserving the maximal amount of intestine. Typically, the bypass will entail connecting a section of the ileum to the ascending or transverse colon.

3. **Aligning the Bowel.** The two bowel segments selected for the anastomosis are aligned side-to-side without tension or twisting. The hepatic or splenic flexure of the transverse colon may require mobilization from its peritoneal attachments to achieve a tension-free connection. The bowel segments are held in position with 2-0 silk stay sutures about 6 cm apart on the antimesenteric border. Two Adson forceps are used to hold up the small bowel serosa laterally and transversely on traction. An electrosurgical blade is used to enter the bowel lumen on its antimesenteric surface (Fig. 43-20.1). The same maneuver is performed on the tenia coli to enter the colon.

FIGURE 43-20.1

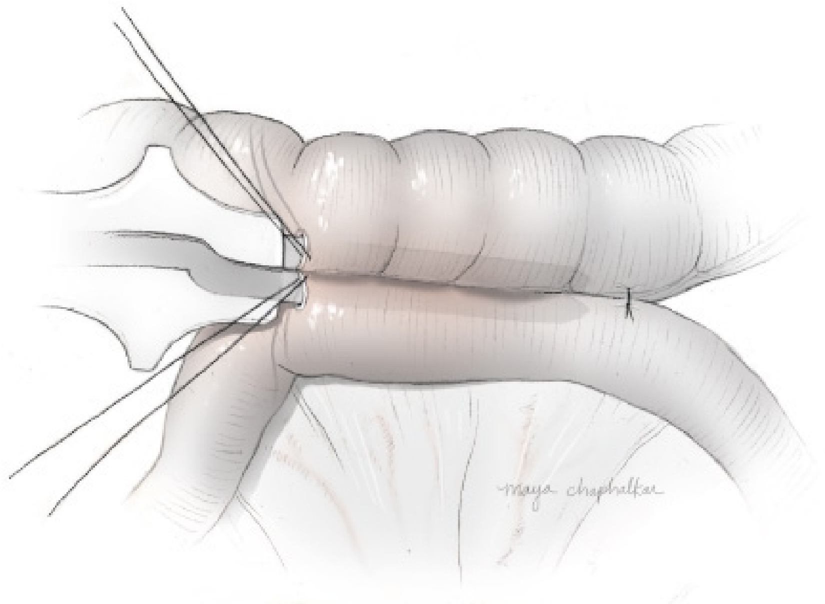


Source: Schorge JO, Schaffer JI, Halvorson LM, Hoffman BL, Bradshaw KD, Cunningham FG: *Williams Gynecology*: http://www.accessmedicine.com

Aligning the bowel.

4. **Performing the Side-to-Side Anastomosis.** One fork of the GIA stapler is inserted into each bowel segment lumen. The bowel is adjusted, if necessary, to position the antimesenteric surfaces between the stapler forks. The stapler then is closed and fired (Fig. 43-20.2). The remaining open defect then can be closed with the TA stapler and the excess bowel trimmed.

FIGURE 43-20.2



Source: Schorge JO, Schaffer JI, Halvorson LM, Hoffman BL, Bradshaw KD, Cunningham FG: *Williams Gynecology*: http://www.accessmedicine.com

Performing the side-to-side anastomosis.

5. **Final Steps.** Occasionally, small bleeding sites will be coagulated electrosurgically on the staple line. The anastomosis also should be palpated to verify an adequate lumen. The bowel should be re-examined to make certain that the connection is watertight and that there is no tension on the anastomosis.

Postoperative

Recovery after bypass surgery should be rapid compared with that following a large resection with anastomosis. In general, a postoperative ileus will resolve in several days, and patients may begin oral alimentation. The underlying clinical situation prompting the need for bypass surgery will dictate most of the clinical course. Relatively minor complications such as fever and wound infection or separation occur commonly. Fistulas, obstruction, anastomotic leaks, abscesses, peritonitis, and perforation are more difficult to manage and often lead to a prolonged postoperative course or death.

Blind loop syndrome is a condition of vitamin B_{12} malabsorption, steatorrhea, and bacterial overgrowth of the small intestine. The usual scenario is a bypass procedure that leaves a segment of nonfunctional, severely irradiated bowel behind. Stasis of the intestinal contents leads to dilatation and mucosal inflammation. Symptoms resemble a partial small bowel obstruction and include nausea, vomiting, diarrhea, bloating, abdominal distention, and pain. Bowel perforation is possible.

Antibiotics often will alleviate the condition, but recolonization and resumption of the blind loop syndrome are common (Swan, 1974). The only definitive therapy for recurrent episodes is exploration with resection of the bypassed segment. To avoid this syndrome, a surgeon may intraoperatively divide the bowel proximal and distal to the lesion and perform a side-to-side anastomosis. The closed loop can be relieved by creation of a mucus fistula at the abdominal wall.

43-21 APPENDECTOMY

Removal of the appendix may be indicated during gynecologic surgery for a variety of reasons. The need, however, is commonly not recognized until an operation is already underway because signs and symptoms of a number of benign gynecologic conditions can mimic appendicitis (Bowling, 2006; Fayez, 1995; Stefanidis, 1999).

In addition, malignancies may involve the appendix. Ovarian cancer frequently metastasizes to the appendix and thereby warrants removal (Ayhan, 2005; Fontanelli, 1992). Primary tumors of the appendix are rare but commonly metastasize to the ovaries (Gehrig, 2002). Pseudomyxoma peritonei is the classic type of mucinous tumor of appendiceal origin that spreads to the ovaries and may implant throughout the abdomen (Prayson, 1994).

Elective coincidental appendectomy is defined as the removal of an appendix at the time of another surgical procedure unrelated to appreciable appendiceal pathology. Possible benefits include preventing a future emergency appendectomy and excluding appendicitis in patients with chronic pelvic pain or endometriosis. Other groups that may benefit include women in whom pelvic or abdominal radiation or chemotherapy is anticipated, women undergoing extensive pelvic or abdominal surgery in which major adhesions are anticipated postoperatively, and patients such as the developmentally disabled in whom making the diagnosis of appendicitis may be difficult because of diminished ability to perceive or communicate symptoms (American College of Obstetricians and Gynecologists, 2005). Most studies suggest that there is little, if any, increased morbidity associated with elective coincidental appendectomy at the time of gynecologic surgery, whether performed during laparotomy or during laparoscopy (Salom, 2003).

Preoperative

Specific preoperative tests or preparations are not required prior to appendectomy. In general, the consenting process for gynecologic surgery should include a discussion of possible "other indicated procedures" such as appendectomy when anticipated intraoperative findings and the potential for performing an appendectomy are uncertain.

There is a small increased risk of nonfatal complications associated with appendectomy (American College of Obstetricians and Gynecologists, 2005). Hematoma formation at the mesoappendix may cause an ileus or partial small bowel obstruction. Perforation of the stump is rare and typically follows insecure suture placement.

Intraoperative

Surgical Steps

1. **Anesthesia and Patient Positioning.** Appendectomy is performed under general anesthesia in the supine position. Postoperative hospitalization is individualized and depends on concurrent surgeries and associated clinical symptoms.

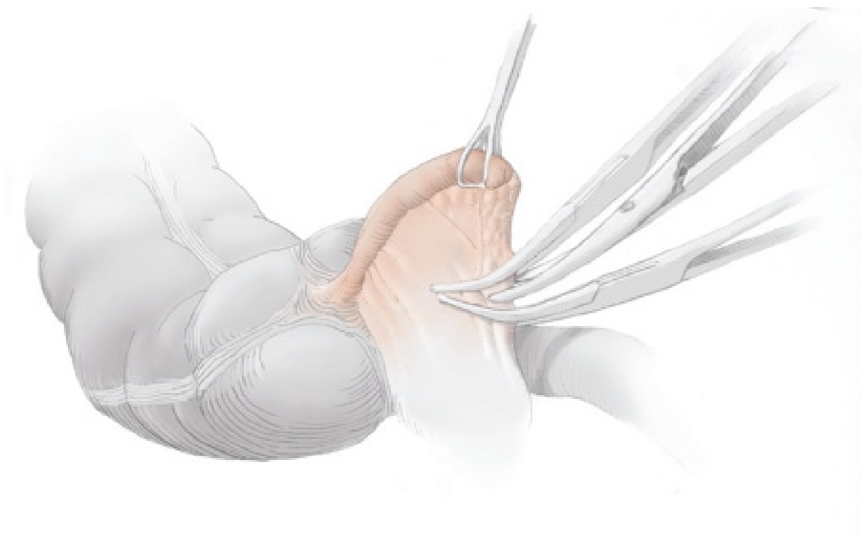
2. **Abdominal Entry.** Appendectomy can be performed through almost any incision. A laparoscopic approach or an oblique McBurney incision in the right lower quadrant of the abdomen traditionally is selected for appendectomy. However, in gynecologic cases, the needs of planned concurrent procedures commonly will dictate incision choice.

3. **Locating the Appendix.** The appendix is located by first grasping the cecum and gently elevating it upward into the incision. Insertion of the terminal ileum should be visible, and the appendix typically is obvious at this point. Infrequently, an appendix is retrocecal or otherwise difficult to identify. In this situation, the convergence of the three teniae coli can be followed to locate the appendiceal base.

4. **Mesoappendix Division.** The appendix tip is elevated with a Babcock clamp, and the cecum is held laterally to place the mesoappendix on gentle traction. The appendiceal artery usually is very difficult to distinguish reliably because of abundant surrounding fatty tissue. Thus, curved hemostats are used to successively clamp the mesoappendix and its vessels to reach the appendiceal base (Fig. 43-21.1).

   The first hemostat is placed horizontallyâ€”aiming directly toward the base of the appendix. The second hemostat is placed at a 30-degree angle so that the tips meet but Metzenbaum scissors have room to cut between the two clamps. The mesoappendix pedicle is ligated with 3-0 delayed-absorbable suture. This step typically is repeated once or twice to comfortably reach the base of the appendix.

FIGURE 43-21.1



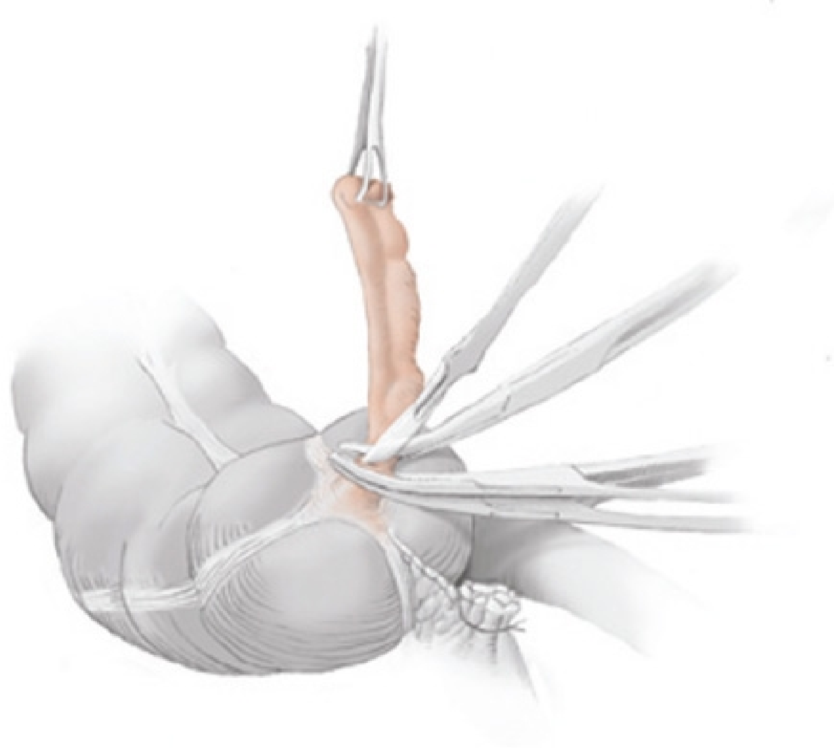
Source: Schorge JO, Schaffer JI, Halvorson LM, Hoffman BL, Bradshaw KD, Cunningham FG: *Williams Gynecology*: http://www.accessmedicine.com

Clamping the mesoappendix.

5. **Appendix Ligation.** At this point, the appendix has been isolated completely from the mesoappendix and is still held vertically by a Babcock clamp. A first hemostat is placed at the appendiceal base, and a second is positioned directly above (Fig. 43-21.2). A third hemostat is closed with a few millimeters of intervening tissue to allow for passage of a knife blade. The knife then cuts between the second and third clamps, and the appendix is removed. The "contaminated" knife and appendix then are handed off the field.

   A 2-0 silk suture is placed beneath the first hemostat with removal of that clamp. A separate suture is placed underneath the second hemostat for added security of the appendiceal stump. Gentle electrosurgical coagulation at the stump surface also may be performed.

FIGURE 43-21.2



Source: Schorge JO, Schaffer JI, Halvorson LM, Hoffman BL, Bradshaw KD, Cunningham FG: *Williams Gynecology*: http://www.accessmedicine.com

Ligation of the appendix.

6. **Final Steps.** There is no need to invert the stump or to place a purse-string suture around it. The cecum may be returned to the abdomen and remaining concurrent surgeries completed.

Postoperative

Patient care postoperatively is dictated by other surgeries performed. Delayed initiation of oral intake or administration of additional antibiotics is not required for appendectomy alone.

43-22 RADICAL PARTIAL VULVECTOMY

To reduce the high morbidity of curative surgery for vulvar cancer without sacrificing cure, a less extensive resection than complete radical vulvectomy may be used. Women with well-localized, unifocal, clinical stage I invasive lesions are ideal candidates (Stehman, 1992). *Radical partial vulvectomy* is a somewhat ambiguously defined operation. It generally refers to complete removal of the tumor-containing portion of the vulvaâ€”wherever it is locatedâ€—with 1- to 3-cm skin margins and excision to the *perineal membrane* . This membrane was previously termed the inferior fascia of the urogenital diaphragm and may also be referred to as the deep perineal fascia. *Radical hemivulvectomy* refers to a larger resection that may be anterior, posterior, right, or left.

The chief concern in performing a less extensive operation for vulvar cancer is the possibility of an increased risk of local recurrence from multifocal disease. However, survival after partial or complete radical vulvectomy is comparable if negative margins are obtained (Farias-Eisner, 1994; Lin, 1992; Scheistroen, 2002). Following less aggressive surgical resection, 10 percent of patients will develop a recurrence at the ipsilateral vulva, and this may be treated by re-excision (Desimone, 2007).

Preoperative

PATIENT EVALUATION

Biopsy confirmation of invasive cancer is an obvious necessity. Squamous lesions with less than 1 mm of invasion may be managed adequately with only wide local excision (see Chap. 31, Lymphatic Vascular Space Invasion). In general, patients undergoing radical partial vulvectomy should not require reconstructive grafts or flaps to cover operative defects.

CONSENT

Morbidity after radical vulvar surgery is common. Wound separation or cellulitis develops frequently. Long-term changes may include displacement of the urine stream, dyspareunia, vulvar pain, and sexual dysfunction. Surgeons should be sensitive to these possible sequelae and counsel the patient appropriately, emphasizing the curative intent and limited scope of the operation.

PATIENT PREPARATION

Bowel preparation may be indicated with posteriorly located resections.

Intraoperative

Surgical Steps

1. **Anesthesia and Patient Positioning.** Radical partial vulvectomy has been performed under local anesthesia combined with sedation in medically compromised patients (Manahan, 1997). However, regional or general anesthesia typically is required.

   Inguinal lymphadenectomy (see Section 43-24, Inguinal Lymphadenectomy) typically is performed before vulvar resection. Patients then may be repositioned to provide full exposure to the vulva, and the vulva is surgically prepared.

2. **Radical Partial Vulvectomy: Variations.** The area of tissue to be removed when radically excising a small cancer depends on the size and location of the tumor (Fig. 43-22.1). The dotted line indicates a planned skin incision for: (*A*) a 1-cm right labia majora tumor and planned 2-cm surgical margins; (*B*) a 2.5-cm periclitoral tumor, which requires an anterior hemivulvectomy; and (*C*) a 2.5-cm midline posterior fourchette tumor requiring posterior hemivulvectomy.

FIGURE 43-22.1

Source: Schorge JO, Schaffer JI, Halvorson LM, Hoffman BL, Bradshaw KD, Cunningham FG: *Williams Gynecology*: http://www.accessmedicine.com

Partial radical vulvectomy: variations.

3. **Right Hemivulvectomy: Making the Lateral Incision.** The planned excision is drawn on the vulva with a surgical

marking pen to provide 2-cm margins (Fig. 43-22.2). Tapering the incision anteriorly and posteriorly will aid a tension-free closure. The lateral skin incision is made with a knife (no. 15 blade) into the skin and subcutaneous fat.

Forceps are used to place the skin edges on traction and aid electrosurgical dissection downward and lateral until reaching the perineal membrane (Fig. 43-22.3). An index finger then can be used to develop the plane between the fat pad of the labia majora and the subcutaneous tissue of the lateral thigh.

FIGURE 43-22.2

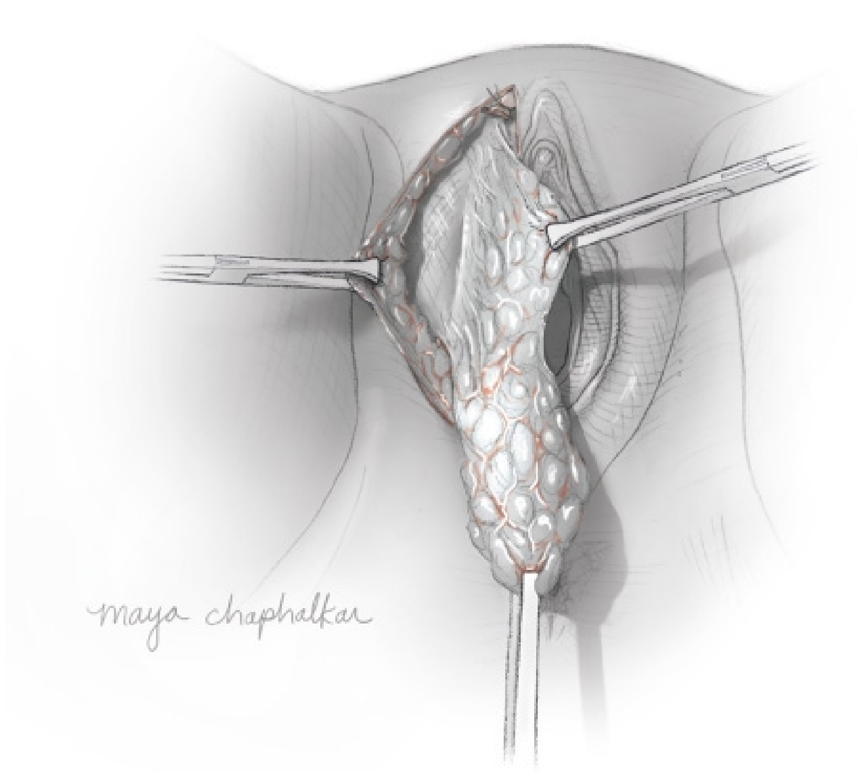
Right hemivulvectomy: lateral dissection to the fascia lata.

4. **Right Hemivulvectomy: Completing the Resection.** The lateral plane that has been developed is extended medially by blunt and electrosurgical dissection along the perineal membrane. The skin edge of the specimen then is placed on lateral traction, and the medial (vaginal mucosa) incision is incised from anterior to posterior. The labial fat pad is transected anteriorly, and the entire radical right hemivulvectomy specimen is placed on downward traction to aid final dissection along the mucosal incision in an anterior-to-posterior direction (Fig. 43-22.4). The specimen is marked at 12 o'clock and examined to ensure adequate margins.

FIGURE 43-22.4



Source: Schorge JO, Schaffer JI, Halvorson LM, Hoffman BL, Bradshaw KD, Cunningham FG: *Williams Gynecology*: http://www.accessmedicine.com

Right hemivulvectomy: removal of the specimen.

5. **Right Hemivulvectomy Closing the Defect.** A gauze sponge may be held firmly in the cavity and rolled downward to guide the electrosurgical blade in achieving hemostasis. The defect then can be irrigated and evaluated to determine requirement for a tension-free closure while minimizing anatomic distortion (Fig. 43-22.5). Several pedicles are visible, particularly at the vaginal margin, where vessels were clamped and tied. In general, lateral undermining of the subcutaneous tissue will provide sufficient mobility to allow primary closure. Interrupted delayed-absorbable sutures are used to create a layered re-approximation of deeper tissues. Interrupted vertical mattress sutures with knots placed laterally are used to close the skin (Fig. 43-22.6).

Right hemivulvectomy: closure of the surgical defect.

6. **Anterior Hemivulvectomy.** This variation requires removal of the clitoris and partial resection of the labia minora, labia majora, and mons pubis. The most anterior portion of the incision is created first on the mons and carried down to the aponeurosis over the pubic symphysis. The specimen is reflected posteriorly to guide dissection. In the midline, the clitoral vessels are clamped and divided separately. The posterior incision is made above the urethral meatus with careful attention to Foley catheter location to avoid urethral injury. Layers of interrupted delayed-absorbable sutures are used to close the defect. Usually, the area surrounding the urethral meatus should be left to granulate secondarily.

7. **Posterior Hemivulvectomy.** This variation entails removal of a portion of the labia majora, Bartholin glands, and upper perineal body. It is generally necessary to compromise the deep margin in this resection because of anal sphincter and rectum proximity. The skin is first incised posteriorly, and a finger is placed into the rectum to guide proximal dissection. The specimen is retracted upward gradually off the sphincter. Dissection proceeds laterally until the anterior margin at the introitus can be incised to complete the resection. The perineal body will need to be re-inforced with interrupted sutures of delayed-absorbable material to provide bulk and to allow re-approximation of skin edges for a tension-free closure. Rectal examination should be performed at the end of surgery to confirm the absence of stitches or stenosis. Incontinence of flatus or stool may develop postoperatively despite efforts to preserve the sphincter.

8. **Partial Urethral Resection (Optional).** If an anterior lesion encroaches on the urethral meatus, then a distal urethrectomy may be required to achieve a cancer-free margin. Radical partial vulvectomy otherwise should be completed almost entirely. The urethra may be transected anywhere distal to the pubic arch. The length of resection is measured first against the Foley catheter. The meatus is held with an Allis clamp, and the specimen is placed on traction. The posterior urethra is incised with a knife, and the underlying mucosa is sewn to the adjacent wall with 4-0 delayed-absorbable suture at the 6 o'clock position. The urethral incision is extended laterally with additional sutures at 3 and 9 o'clock until the proximal portion of the Foley can be transected and removed from the bladder. The transection is completed, and a final stitch is placed at 12 o'clock.

Partial or total urinary incontinence may be alleviated somewhat by urethral plication in some cases.

9. **Final Steps.** Suction drains typically are not required but should be at least considered in some circumstances. Copious irrigation is indicated at various times during closure of the defect to minimize infection postoperatively. No formal dressing is applied at the end of surgery. However, fluffed-out gauze may be placed at the perineum and held in place with mesh underwear to tamponade any subcutaneous bleeding and to promote a clean and dry operative site in the immediate postoperative period.

Postoperative

Meticulous care of the vulvar wound is mandatory to prevent morbidity. The vulva should be kept dry by use of a blow dryer or fan. Within a few days, brief sitz baths or bedside irrigation followed by air drying will help to keep the incision clean. Patients should be instructed not to wear underwear in the hospital. Discharge instructions also should encourage loose-fitting gowns to aid healing and efforts to minimize wound tension.

Incision separation is the most common postoperative complication and often will involve only a portion of the incision (Burke, 1995). The wound should be dÃ©brided if necessary, and efforts to keep the site clean and dry are continued. Granulation tissue eventually will allow healing by secondary intention, but recovery time will be extended significantly.

Sexual dysfunction may relate to a sense of disfigurement. Scarring also may result in discomfort or an alteration in sensation that affects a woman's sexual satisfaction. Sensitivity to these concerns will enable a dialogue to develop that can lead to possible management options.

43-23 RADICAL COMPLETE VULVECTOMY

If cancers are so extensive that no meaningful portion of the vulva can be preserved, radical complete vulvectomy is indicated over the more limited procedureâ€"radical partial vulvectomy. The operation typically is performed through three separate incisions: one each for the vulvectomy and bilateral inguinal lymphadenectomy. Intact skin lies between these incisions to aid wound healing. The en bloc incision, colloquially termed the *butterfly* or *longhorn* incision, was used traditionally to remove these skin bridges and the underlying lymphatic channels that potentially harbored "in transit" tumor emboli (see Fig. 31-5A). (Gleeson, 1994). However, such recurrences are rare, and the en bloc technique largely has been abandoned (Rose, 1999). Thus, the three-incision procedure is preferred because survival rates are equivalent and major morbidity is reduced dramatically (Helm, 1992)

Removal of an entire vulvar lesion with an adequate 2-cm margin usually creates a large surgical defect. In some cases, wound margins may be closed primarily without tension by undermining and mobilizing adjacent tissues. On other occasions, a split-thickness skin graft, lateral skin transposition, rhomboid flap, or other reconstructive procedure will be indicated to reduce the chances of wound separation (see Section 43-26, Reconstructive Grafts and Flaps).

Preoperative

PATIENT EVALUATION

Biopsy confirmation of invasive cancer should precede surgery. Confluent squamous lesions with less than 1 mm of invasion may be managed adequately by skinning vulvectomy (see Section 43-25, Skinning Vulvectomy). Depending on the location of the tumor, the clitoral-sparing modification of radical complete vulvectomy also is an option (Chan, 2004). Frequently, patients are elderly, obese, or have significant coexisting medical problems that must be considered.

CONSENT

Major morbidity is common soon after radical complete vulvectomy, and partial wound separation or cellulitis occurs frequently. Complete wound breakdown is more problematic, and weeks of aggressive hospital care may be required to promote secondary healing. Premature hospital discharge may result in poor home wound care. Resulting tissue necrosis often requires re-admission and surgical dÃ©bridement.

Long-term changes may include displacement of the urine stream, dyspareunia, vulvar pain, and sexual dysfunction. Accordingly,

surgeons should be aware of possible sequelae and counsel appropriately. Emphasis is placed on the curative intent of the operation and the need for adequate tumor-free margins to lessen local recurrence risks.

PATIENT PREPARATION

Bowel preparation may be indicated with posteriorly located lesions. Antibiotic prophylaxis has not been shown to reduce wound infection or breakdown (Hopkins, 1993).

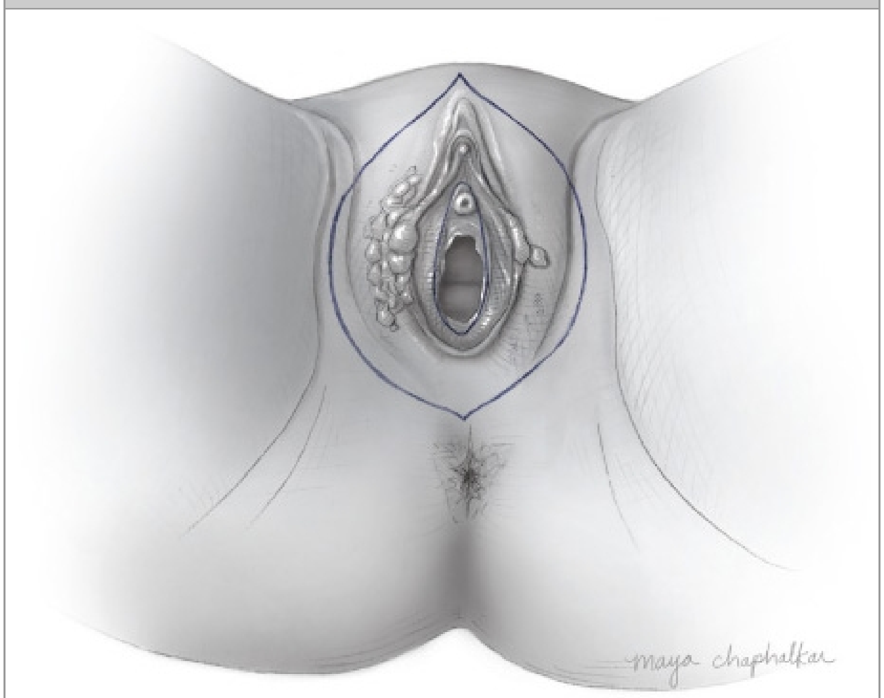
Intraoperative

Surgical Steps

1. **Anesthesia and Patient Positioning.** Regional or general anesthesia is required, and inguinal lymphadenectomy is performed first (see Section 43-24, Inguinal Lymphadenectomy). The patient then is placed in dorsal lithotomy position. Exposure and surgical preparation of the operative field should be planned to accommodate resection and reconstruction.

2. **Planning the Skin Incision.** The medial and lateral incisions are drawn to encompass the tumor and provide a 2-cm margin around the tumor. The clitoris is included if necessary. Tapering the incision anteriorly and posteriorly also will aid a tension-free closure (Fig. 43-23.1).

FIGURE 43-23.1



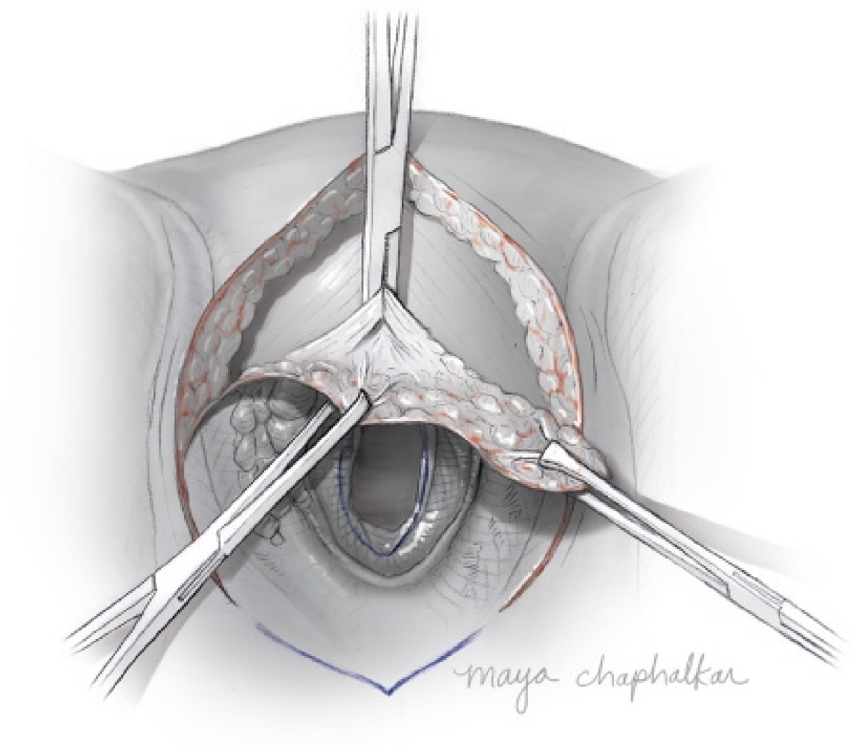
Source: Schorge JO, Schaffer JI, Halvorson LM, Hoffman BL, Bradshaw KD, Cunningham FG: *Williams Gynecology*: http://www.accessmedicine.com

Incisions.

3. **Anterior Dissection.** The skin incision begins anteriorly with the knife (no. 15 blade) cutting into the subcutaneous fat. The incision is extended downward about three quarters of its length. The remainder of the posterior incision is completed later to decrease bleeding. Much of the anterior dissection is described in the preceding section on radical partial vulvectomy (see Section 43-22, Radical Partial Vulvectomy, Step 6). Briefly, the incision is carried down to the pubic aponeurosis. The

specimen is reflected downward on traction to guide dissection. The vascular base of the clitoris is clamped in the midline, transected, and suture ligated with delayed-absorbable suture (Fig. 43-23.2). Electrosurgical dissection then proceeds dorsally off the pubic bone until the medial incision line is reached anteriorly. The medial incision is made above the urethral meatus to avoid injury to the urethra unless a distal urethrectomy is required (see Section 43-22, Radical Partial Vulvectomy, Step 8).

FIGURE 43-23.2

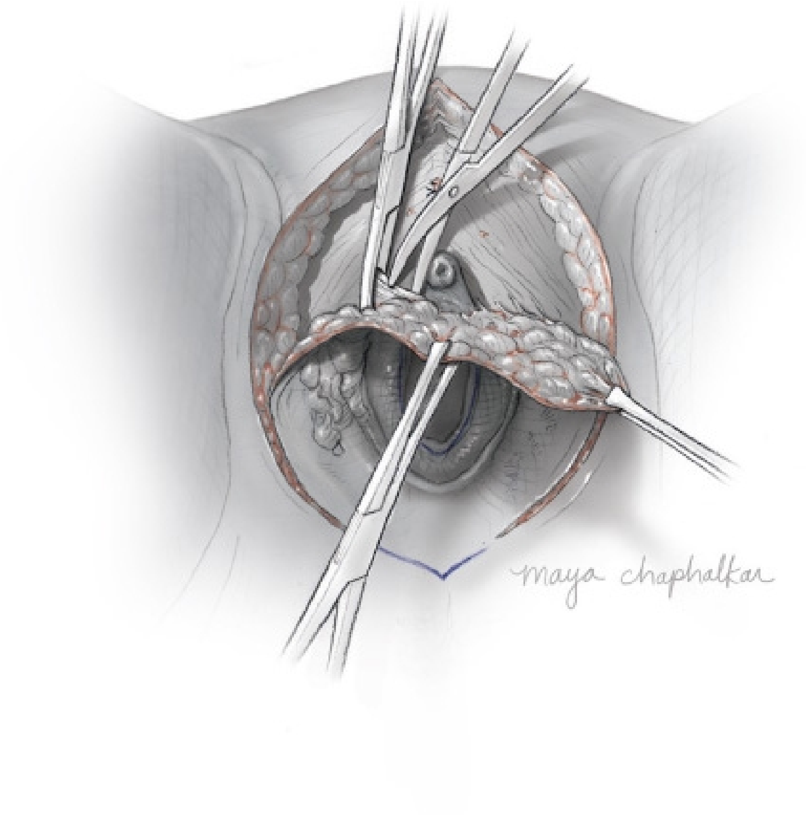


Source: Schorge JO, Schaffer JI, Halvorson LM, Hoffman BL, Bradshaw KD, Cunningham FG: *Williams Gynecology*: http://www.accessmedicine.com

Anterior dissection.

4. **Lateral Dissection.** Blunt finger dissection is performed to establish a plane lateral to the labial fat pads along the perineal membrane. The vulvectomy specimen is placed on traction to guide electrosurgical dissection medially to reach the vaginal wall. Vascular vestibular tissue along the sides of the vagina will need to be clamped, cut, and ligated to reduce bleeding (Fig. 43-23.3).

FIGURE 43-23.3

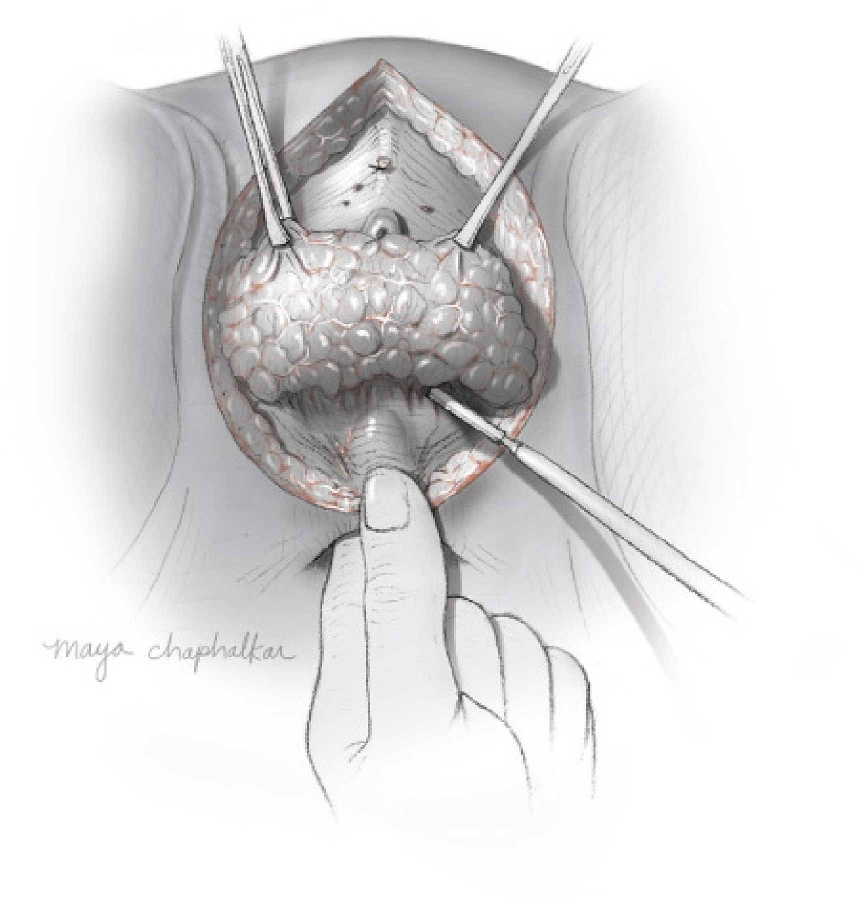


Source: Schorge JO, Schaffer JI, Halvorson LM, Hoffman BL, Bradshaw KD, Cunningham FG: *Williams Gynecology*: http://www.accessmedicine.com

Medial dissection.

5. **Posterior Dissection.** The outer skin incision is completed with a knife as the vulvectomy proceeds posteriorly. A finger then is placed into the rectum to prevent inadvertent injury, and the specimen now is held upward on traction. Electrosurgical dissection extends the outer incisions along the perineal membrane to the midline. The dissection continues anteriorly away from the anus until the medial incision can be made to detach the radical complete vulvectomy specimen (Fig. 43-23.4).

FIGURE 43-23.4



Source: Schorge JO, Schaffer JI, Halvorson LM, Hoffman BL, Bradshaw KD, Cunningham FG: *Williams Gynecology*: http://www.accessmedicine.com

Posterior dissection.

6. **Evaluating the Specimen.** A stitch is placed at 12 o'clock on the specimen to orient the pathologist. Skin retraction of the specimen will make it appear narrower. However, it should be inspected carefully to assess its margins. Additional lateral or medial tissue margins can be sent separately if necessary. Alternatively, a frozen section analysis can be requested to evaluate an equivocal margin.

7. **Closing the Defect.** The wound is copiously irrigated, and hemostasis is achieved with a combination of electrosurgical coagulation, clamping, and suturing. The defect then is evaluated to determine the best method of closure (Fig. 43-23.5).

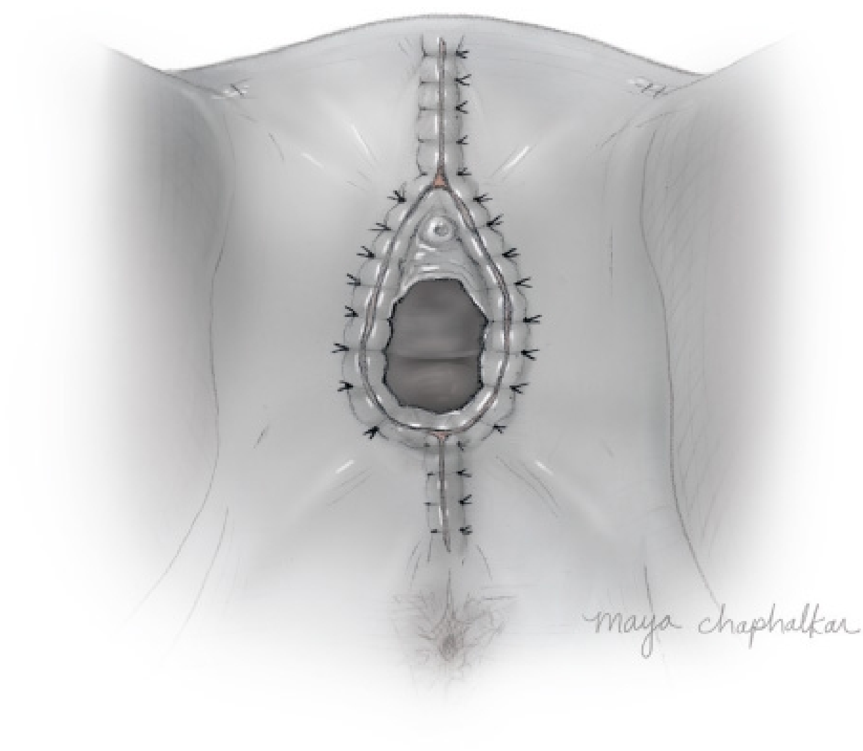
   Undermining lateral tissues will aid a tension-free primary closure. Deeper tissues are first re-approximated with interrupted delayed-absorbable suture. The vulvar skin then is closed with vertical mattress stitches using delayed-absorbable suture (Fig. 43-23.6). No stitches are placed between the skin and urethra if this displaces the urethra or creates tension on it. In such cases, this area will heal secondarily by granulation.

FIGURE 43-23.5

Source: Schorge JO, Schaffer JI, Halvorson LM, Hoffman BL, Bradshaw KD, Cunningham FG: *Williams Gynecology*: http://www.accessmedicine.com

Surgical defect.

FIGURE 43-23.6



Source: Schorge JO, Schaffer JI, Halvorson LM, Hoffman BL, Bradshaw KD, Cunningham FG: *Williams Gynecology*: http://www.accessmedicine.com

Simple closure.

8. **Final Steps.** Suction drains do not prevent wound infection or breakdown but may be considered in some cases if there is a large defect (Hopkins, 1993). If primary closure is performed, then fluffed-out gauze may be placed at the perineum and held in place with mesh underwear to keep the operative site clean and dry in the immediate postoperative period.

Postoperative

If a primary closure is performed, postoperative care is essentially the same as described for patients undergoing radical partial vulvectomy (see Section 43-22, Radical Partial Vulvectomy). Because of a larger operative defect, the likelihood of morbidity is increased correspondingly. Management of reconstructive grafts and flaps is reviewed in Section 43-26, Reconstructive Grafts and Flaps.

43-24 INGUINAL LYMPHADENECTOMY

The main indication for removal of groin nodes is staging surgery for vulvar cancer. Inguinal metastases are the most significant prognostic factor in vulvar squamous cancer, and their detection requires additional therapy (see Chap. 31, Lymphadenectomy) (Homesley, 1991). However, the utility of this dissection is more controversial in the management of vulvar malignant melanoma, and the presence of positive nodes generally is only of prognostic value. Lastly, in women with ovarian or uterine cancer, suspicion of inguinal metastases will prompt removal.

The proper extent of an inguinal lymphadenectomy for vulvar cancer is controversial and varies widely. The terminology is also inconsistent. Based on a survey of gynecologic oncologists, the most common procedure is a superficial (above the cribriform fascia) inguinal lymphadenectomy with (40 percent) or without (34 percent) additional removal of some deeper nodes medial to the femoral vein. Fewer practitioners (22 percent) resect all the deep nodes below the cribriform fascia (Levenback, 1996).

In general, lymphatic drainage from the vulva rarely bypasses the superficial nodes, and a superficial node dissection is adequate for small tumors (see Fig. 31-2). For most others, removal of the deep nodes within the fossa ovalis generally is advisable and may be performed safely with preservation of the cribriform fascia (Bell, 2000). Unroofing the cribriform fascia to remove the deep nodes usually is not recommended because of the unacceptable risks of major morbidity, such as erosion of the skeletonized femoral vessels to the overlying skin flap.

The emergence of sentinel lymph node mapping is a promising modality that has demonstrated vast potential in reducing the radicality of the surgery (see Chap. 31, Sentinel Node Biopsy). (Moore, 2003). However, the clinical implications of this approach and the best technique remain unproven. Groin relapses following a negative sentinel node biopsy emphasize the need for further investigation (Frumovitz, 2004). Implementation of this experimental strategy awaits completion of a prospective Gynecologic Oncology Group study (protocol 173).

Preoperative

PATIENT EVALUATION

Clinical palpation is not an accurate means to evaluate the groin nodes (Homesley, 1993). Magnetic resonance (MR) imaging and positron-emission tomographic (PET) scanning are also relatively insensitive (Bipat, 2006; Cohn, 2002; Gaarenstroom, 2003). Sentinel node identification appears to be the most promising diagnostic test to emerge for excluding the presence of inguinal metastases (Selman, 2005). Fixed, large, clinically obvious groin metastases that appear unresectable should be treated preoperatively with radiation before attempting removal.

CONSENT

Patients should understand the need for unilateral or bilateral groin dissection and its relationship to their cancer treatment. They should be prepared for a potentially several-week recovery in which postoperative complications are common and may include cellulitis, wound breakdown, lymphedema, and lymphocyst formation. These events may develop within a few days, several months, or even years later. In contrast, intraoperative complications are less common, and hemorrhage from the femoral vessels is encountered rarely.

PATIENT PREPARATION

When both groins are dissected, a two-team approach is ideal to reduce operative time. Prophylactic antibiotics may be administered but have not been shown to prevent complications (Gould, 2001).

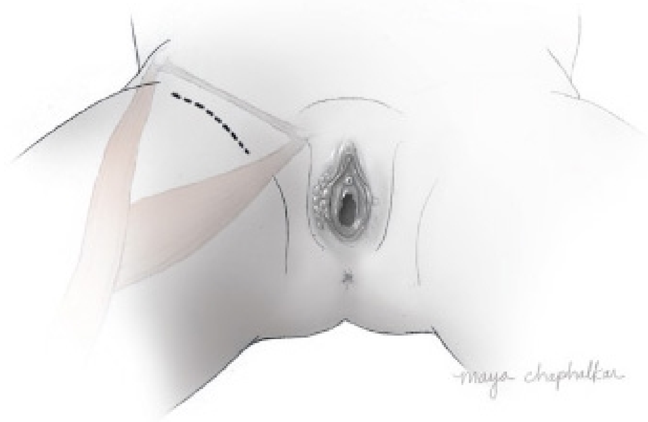
Intraoperative

Surgical Steps

1. **Anesthesia and Patient Positioning.** General or regional anesthesia may be used. Inguinal lymphadenectomy is performed prior to radical partial or radical complete vulvectomy (see Sections 43-22, Radical Partial Vulvectomy and 43-23, Radical Complete Vulvectomy). Legs should be placed in Allen stirrups in low lithotomy position, abducted about 30 degrees, and flexed minimally at the hip to flatten the groin (see Fig. 40-6). Rotation of the thigh a few degrees outward will open the femoral triangle.

2. **Skin Incision.** The groin is incised 2 cm below and parallel to the inguinal ligament starting 3 cm distal and medial to the anterosuperior iliac spineâ€”aiming toward the adductor longus tendon (Fig. 43-24.1). The incision is 8 to 10 cm long and is taken through full skin thickness and 3 to 4 mm into the fat.

FIGURE 43-24.1

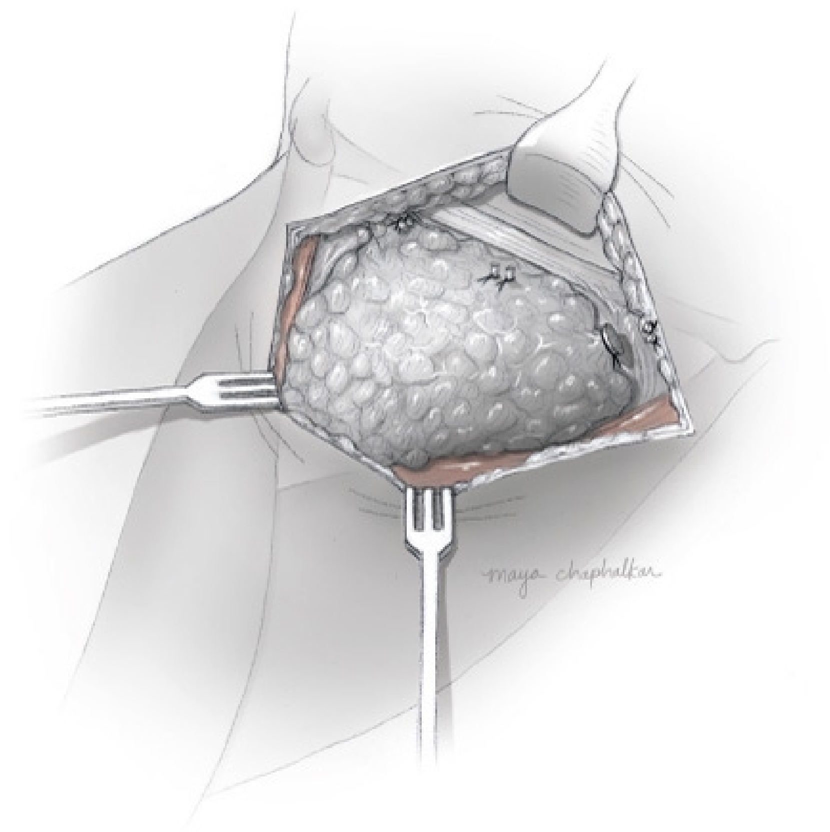


Incisions.

3. **Developing the Upper Flap.** Adson forceps with teeth elevate and provide traction to the dermal surface of the upper skin while a hemostat is opened underneath to begin dissection. Dissection continues down through the subcutaneous fat and Scarpa fasciaâ€”aiming for a position in the midline of the incision 3 cm above the inguinal ligament. Dissection proceeds downward until the glistening white aponeurosis of the external oblique muscle is identified. Adson forceps then are replaced with skin hooks to provide better traction.

   A semicircle of fatty tissue is rolled inferiorly and laterally along the aponeurosis using electrosurgical dissection and intermittent blunt dissection. During dissection, the superficial circumflex iliac vessels are clamped and ligated (Fig. 43-24.2). Additionally, superficial epigastric and superficial external pudendal vessels are clamped and tied as they are encountered (see Fig. 38-3). Dissection proceeds until the lower margin of the inguinal ligament is exposed.

FIGURE 43-24.2



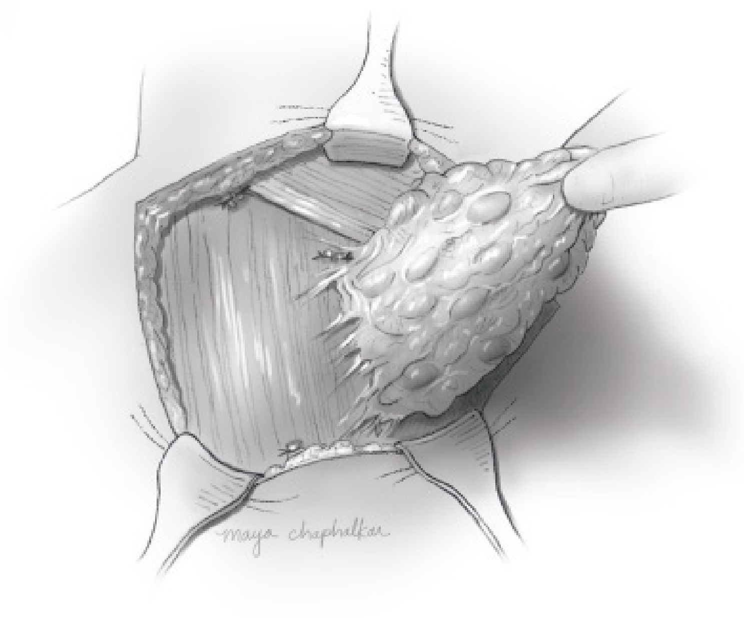
Source: Schorge JO, Schaffer JI, Halvorson LM, Hoffman BL, Bradshaw KD, Cunningham FG: *Williams Gynecology*: http://www.accessmedicine.com

Dissection of the upper flap.

4. **Developing the Lower Flap.** In a similar manner to the upper flap, the posterior skin flap is raised. Dissection progresses through the subcutaneous fat to the deep fascia of the thighâ€”aiming approximately 6 cm from the inguinal ligament toward the apex of the femoral triangle (see Fig. 38-29). Blunt finger dissection along the inner portion of the sartorius and adductor longus muscles aids development of the lower flap boundaries. The dissection becomes progressively deeper into the subcutaneous tissue of the thigh but remains superficial to the fascia lata. At the apex of the femoral triangle, the converging tissue is divided to completely encircle the fatty-lymphoid specimen. Dissection is continued circumferentially toward the fossa ovalis. Node-bearing tissue is held on traction to aid its dissection. Venous tributaries are ligated as they are encountered.

5. **Removal of the Superficial Nodes.** The superficial lymph nodes lie within the fatty tissue at various locations along the saphenous, superficial external pudendal, superficial circumflex iliac, and superficial inferior epigastric veins (see Fig. 38-29). The saphenous vein is encountered during the dissection of the medial side of the fat pad. The distal end should be individually transected and ligated with permanent suture for identification (Fig. 43-24.3). If desired, it can be salvaged by dissecting it from the fat pad. Circumferential dissection is performed next to isolate and remove the nodal bundle as it exits the fossa ovalis. The proximal end of the saphenous vein should be ligated separately, if sacrificed. Remaining attachments are dissected from the cribriform fascia or clamped and cut to remove the specimen.

FIGURE 43-24.3



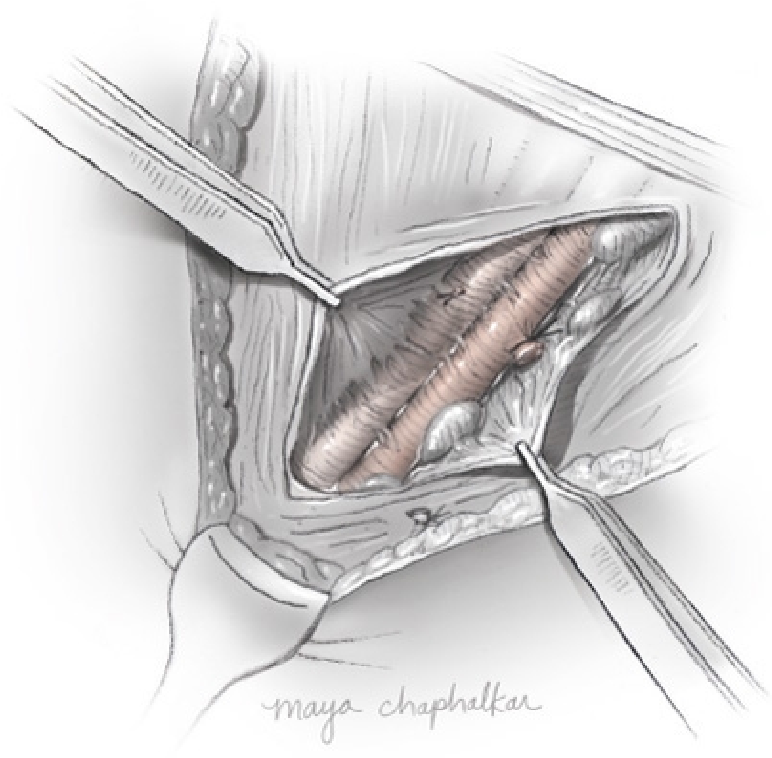
Source: Schorge JO, Schaffer JI, Halvorson LM, Hoffman BL, Bradshaw KD, Cunningham FG: *Williams Gynecology*: http://www.accessmedicine.com

Dissection of the lower flap and removal of the superficial nodes.

6. **Removal of the Deep Nodes.** The femoral vein should be visible within the fossa ovalis. The deep groin nodes are consistently located just medial and parallel to this vessel. Of these, Cloquet node is the uppermost. The residual deep femoral nodal tissue is excised by removing any fatty tissue along the anterior and medial surfaces of the femoral vein above the lower limit of the fossa ovalis. The femoral sheath and cribriform fascia should remain intact if possible.

   If a clinically positive deep node cannot otherwise be reached, the cribriform fascia may be unroofed by making a longitudinal incision distally along the overlying femoral sheath (Fig. 43-24.4). Seven or eight underlying deep inguinal nodes are revealed, and these deep nodes typically are located in a more orderly fashion than the superficial nodes. Fatty lymphoid tissue then is dissected from the anterior and medial surfaces of the femoral vein. Following node removal, the femoral sheath edges then may be reapproximated using delayed-absorbable suture and/or covered with the sartorius muscle.

FIGURE 43-24.4

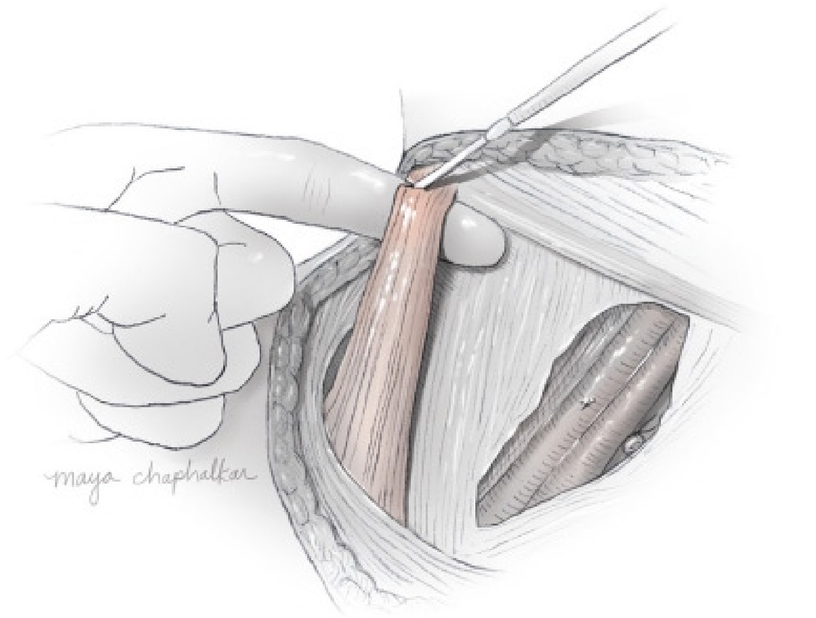


Source: Schorge JO, Schaffer JI, Halvorson LM, Hoffman BL, Bradshaw KD, Cunningham FG: *Williams Gynecology*: http://www.accessmedicine.com

Unroofing the cribiform fascia to remove the deep nodes.

7. **Sartorius Muscle Transposition (Optional).** The fascia lata is incised to allow blunt dissection of the sartorius muscle (Fig. 43-24.5). The proximal sartorius muscle then is transected at its insertion to the anterosuperior iliac spine. A finger is wrapped around the upper part of the muscle to aid electrosurgical blade transection directly off the spine. Transection should be as high as possible, with care taken to avoid the lateral femoral cutaneous nerve. The muscle then is further mobilized to cover the femoral vessels and sutured to the inguinal ligament with delayed-absorbable suture.

FIGURE 43-24.5

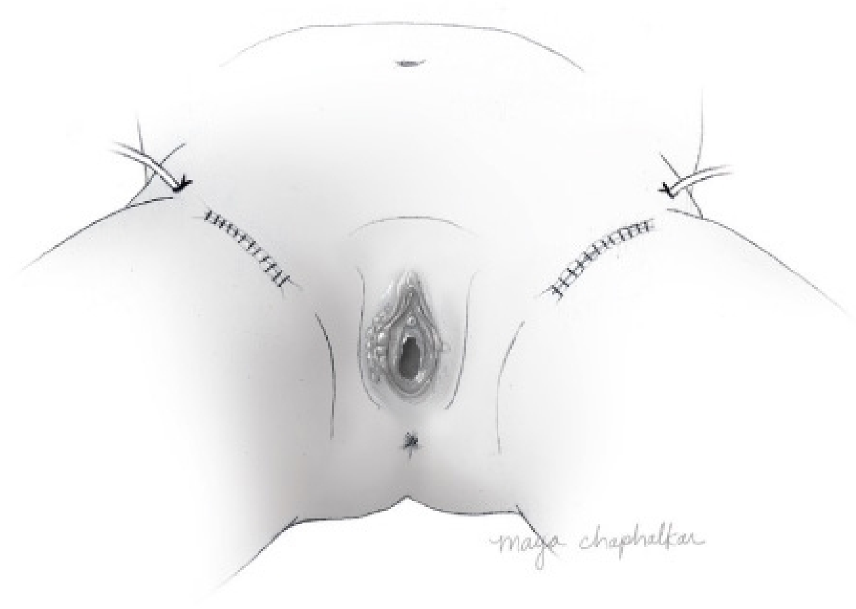


Source: Schorge JO, Schaffer JI, Halvorson LM, Hoffman BL, Bradshaw KD, Cunningham FG: *Williams Gynecology*: http://www.accessmedicine.com

Sartorius muscle transposition.

8. **Wound Closure.** The surgical defect should be examined carefully, made hemostatic, and irrigated. The groin is closed with layers of delayed-absorbable suture, and a Blake or Jackson-Pratt drain is brought out superolaterally and tied in place with permanent suture (Fig. 43-24.6). Staples are placed to re-approximate skin edges.

FIGURE 43-24.6



Source: Schorge JO, Schaffer JI, Halvorson LM, Hoffman BL, Bradshaw KD, Cunningham FG: *Williams Gynecology*: http://www.accessmedicine.com

Wound closure.

Postoperative

Suction drainage enables the incision to heal and the underlying space to be obliterated. Drain tubing should be milked manually or stripped regularly with the index finger and thumb toward the suction device to prevent blockage. Drains may be removed when output declines to 20 to 25 mL/day. Typically, this requires approximately 2 weeks (Gould, 2001). Premature removal may result in a symptomatic lymphocyst that requires drain re-insertion or outpatient needle aspiration.

The groin incision should be left uncovered and examined regularly. Postoperative complications are very common, particularly wound cellulitis and breakdown. Preoperative radiation and removal of bulky, fixed nodes increase the risk of these complications. Unroofing the deep fascia also can expose the femoral vessels unnecessarily to erosion or sudden hemorrhage. A protective sartorius muscle transposition may be especially indicated in these selected situations to prevent morbidity (Judson, 2004; Paley, 1997).

Chronic lymphedema is another frequent complication of inguinal lymphadenectomy. In most reports, preservation of the saphenous vein has been shown to reduce the incidence (Dardarian, 2006; Gaarenstroom, 2003). Regardless, this condition typically is much more problematic with the addition of groin radiation. Supportive management is meant to minimize the edema and prevent symptomatic progression. Foot elevation, compression stockings, and on occasion, diuretic therapy may be helpful.

43-25 SKINNING VULVECTOMY

The term *skinning vulvectomy* implies a wide, superficial resection that encompasses both sides of the vulva, that is, a complete simple vulvectomy. A less extensive, unilateral procedure is better referred to as a *wide local excision or partial simple vulvectomy* (see Section 41-15, Wide Local Excision of Vulvar Intraepithelial Neoplasia). The usual indication for skinning vulvectomy is a woman with confluent, bilateral vulvar intraepithelial neoplasia (VIN) type 2 or 3 who is not a candidate for directed ablation with carbon dioxide (CO_2) laser or the Cavitron Ultrasonic Surgical Aspirator (CUSA) (see Chap. 40, Cavitational Ultrasonic Surgical Aspiration). Fortunately, patients with such extensive VIN are encountered infrequently. Paget disease without underlying adenocarcinoma and vulvar dystrophies refractory to standard therapy are other rare indications (Ayhan, 1998; Curtin, 1990; Rettenmaier, 1985).

The surgical procedure is straightforward and removes the entire lesion with negative margins. It is distinguished from a radical complete vulvectomy by removal of only the skin surface with preservation of the subcutaneous fat and deeper tissues (see Section 43-23, Radical Complete Vulvectomy). However, the disfiguring result can be psychologically devastating. In addition, the defect is often large and cannot be closed primarily without a split-thickness skin graft (STSG) or other type of flap (see Section 43-26, Reconstructive Grafts and Flaps).

Preoperative

PATIENT EVALUATION

Prior to surgery, vulvoscopy with directed biopsy is required (see Chap. 31, Lesion Evaluation).These steps exclude an invasive squamous lesion of greater than 1 mm depth, which would warrant a more radical procedure. Familiarity with an array of possible STSGs or flaps is crucial to planning the operation in the event primary closure is not possible.

CONSENT

Patients should be informed that other more limited treatment options either have been exhausted or are inappropriate. The surgery may result in significant sexual changesâ€"which may be permanent. Accordingly, surgeons should emphasize that all efforts will be made to restore a functional, normal-appearing vulva. Fortunately, most physical complications will be minor, such as cellulitis or partial wound dehiscence.

PATIENT PREPARATION

Complete bowel preparation is indicated only if perianal skin is to be excised. Otherwise, enemas are sufficient. Prophylactic antibiotics typically are given. Selection of a donor site for STSG is described in Section 43-26, Reconstructive Grafts and Flaps.

Intraoperative

Surgical Steps

1. **Anesthesia and Patient Positioning.** Regional or general anesthesia generally is required. The patient is placed in dorsal lithotomy position, and adjustments provide access to the entire lesion. Vulvar hair should be shaved. Intraoperative vulvoscopy may be needed to better delineate VIN lesion margins.

2. **Skin Incision.** The inner and outer incision lines are drawn to encompass the disease with margins of at least a few millimeters (Fig. 43-25.1). The clitoris may be spared in many patients by making a horseshoe-shaped incision. If preserving the clitoris, an incision begins at its anterolateral margin and is taken through full-skin thickness at least halfway to the perineal body. Inner and outer skin incision margins are created on both sides of the vulva to completely encompass disease.

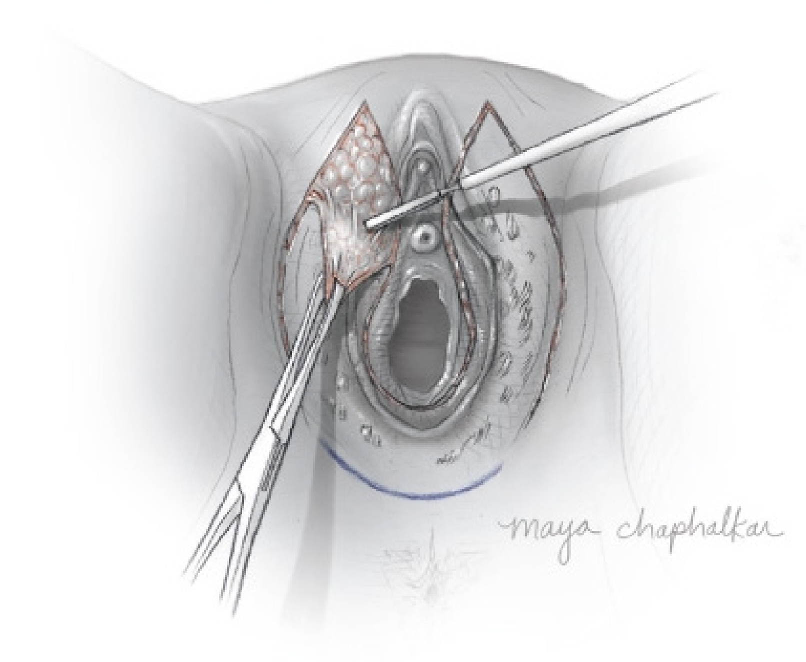
FIGURE 43-25.1

Source: Schorge JO, Schaffer JI, Halvorson LM, Hoffman BL, Bradshaw KD, Cunningham FG: *Williams Gynecology*: http://www.accessmedicine.com

Marking the incisions.

3. **Beginning the Dissection.** The specimen edge then may be reflected with an Allis clamp to provide traction as the avascular plane underneath the skin is dissected from the subcutaneous fatty tissue (Fig. 43-25.2). When the anterior skin edge is large enough, a hand is placed underneath to reflect the specimen more firmly and guide dissection inferiorly. The skin incision then is extended downward along the outer and inner incision margins toward the perineal body. Electrosurgical coagulation is used to achieve hemostasis before repeating the process on the contralateral side.

FIGURE 43-25.2



Source: Schorge JO, Schaffer JI, Halvorson LM, Hoffman BL, Bradshaw KD, Cunningham FG: *Williams Gynecology*: http://www.accessmedicine.com

Performing the dissection.

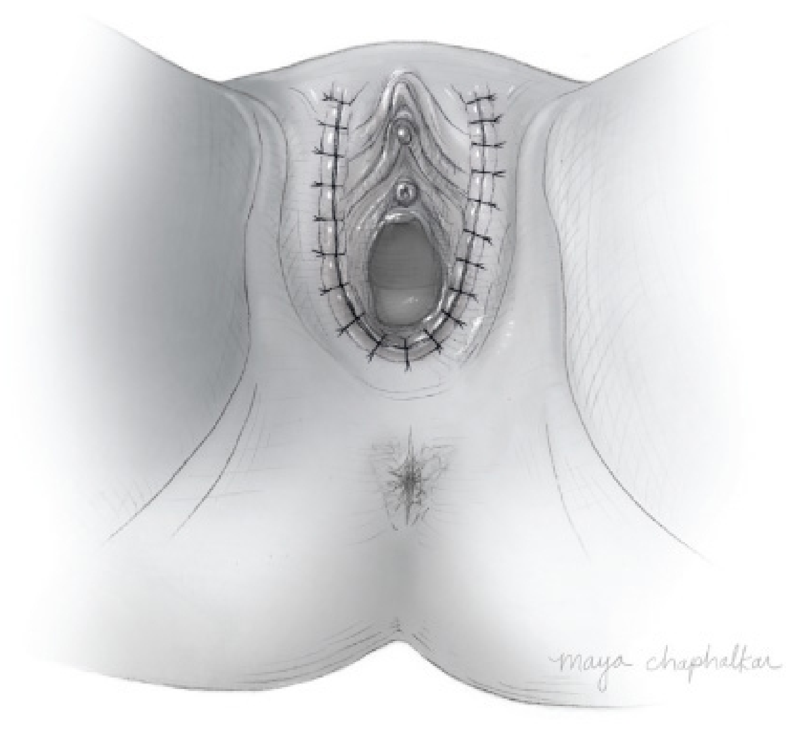
4. **Removal of the Specimen.** The left and right outer skin incisions are joined in the midline superficial to the perineal body. The posterior vulvar tissue is held with an Allis clamp to provide traction for upward dissection toward the inner incision. This portion of the skinning vulvectomy typically is performed last because an avascular tissue plane superficial to the subcutaneous tissue is absent, and bleeding can be brisk. The specimen can be removed following detachment from the inner posterior incision.

   The skinning vulvectomy should be examined carefully to grossly determine the margins. Paget disease or close VIN margins may warrant a frozen section analysis to determine if more tissue requires excision. A stitch should be placed on the specimen to orient the pathologist.

5. **Closure of the Defect.** A dry laparotomy pad is held against the vulvar defect and rolled slowly downward to halt surface bleeding and to aid meticulous electrosurgical coagulation of vessels. The operative site is irrigated and assessed.

   If the width of the defect is sufficiently narrow to permit primary closure, the surrounding tissue is mobilized. Lateral undermining may be particularly useful for a tension-free closure. Vertical mattress delayed-absorbable sutures then are placed circumferentially with the knots positioned laterally (Fig. 43-25.3).

FIGURE 43-25.3



Source: Schorge JO, Schaffer JI, Halvorson LM, Hoffman BL, Bradshaw KD, Cunningham FG: *Williams Gynecology*: http://www.accessmedicine.com

Primary closure.

6. **Final Steps.** A CO_2 laser may be used to vaporize multifocal lesions outside the operative field.

Postoperative

If a primary closure is performed, postoperative care is essentially the same as described for patients undergoing radical partial vulvectomy (see Section 43-22, Radical Partial Vulvectomy). Long-term surveillance is mandatory regardless of margin status to identify recurrent or de novo sites of preinvasive disease (Rettenmaier, 1987).

43-26 RECONSTRUCTIVE GRAFTS AND FLAPS

Primary closure of a vulvar wound typically is not advised if closure of a large defect would create excessive incision tension or if other wound factors are present. In these cases, placing a reconstructive skin graft or flap is preferred to allowing a defect to heal by secondary intention. In general, the simplest procedure that will achieve the best functional result should be selected.

The decision to perform a split-thickness skin graft (STSG), lateral skin transposition, or rhomboid skin flap depends on clinical circumstances and surgeon experience. Variations of these techniques are used commonly in gynecologic oncology (Burke, 1994; Rettenmaier, 1987).

Typical candidates for a skin graft or flap have undergone a large wide local excision, skinning vulvectomy, or partial or complete radical vulvectomy. Myocutaneous flaps, most commonly using the rectus abdominis and gracilis muscles, are used primarily in patients with prior radiation, very large defects, or a need for vaginal reconstruction. However, a full description of the innumerable

types of local flaps is beyond the scope of this section.

Preoperative

PATIENT EVALUATION

Fortunately, a broad range of operative procedures is availableâ€”each with its advantages and disadvantages (Weikel, 2005). The size of the lesion and the anticipated postoperative defect largely will dictate reconstructive options. In some complicated cases, plastic surgical consultation may be indicated.

CONSENT

Many women's body image will be altered significantly following extensive vulvar surgery, and sexual dysfunction may be problematic (Green, 2000). When discussing these effects, patient responses vary widely. Some express minimal concern, whereas others are devastated by the thought of a disfiguring result. Accordingly, counseling is individualized, specifically addressing patient concerns.

In addition, wound separation, infection, and wound healing by secondary intention are common complications. Moreover, patients also should be advised that their disease may recur within a graft or flap (DiSaia, 1995).

PATIENT PREPARATION

Complete bowel preparation generally is indicated for most reconstructions. Because a patient may be relatively immobile postoperatively and the need to prevent wound contamination is absolute, enemas usually are insufficient. In addition, prophylactic antibiotics typically are given. Early ambulation may be detrimental to graft or flap healing. Therefore, to prevent venous thrombosis, use of pneumatic compression devices or subcutaneous heparin is warranted.

For patients undergoing STSG, the hip, buttock, and inner thigh should be examined carefully. The selected donor sites should contain healthy skin, be hidden by the patient's clothing postoperatively, and be accessible in the operating room. Typically, a graft is taken from the upper thigh.

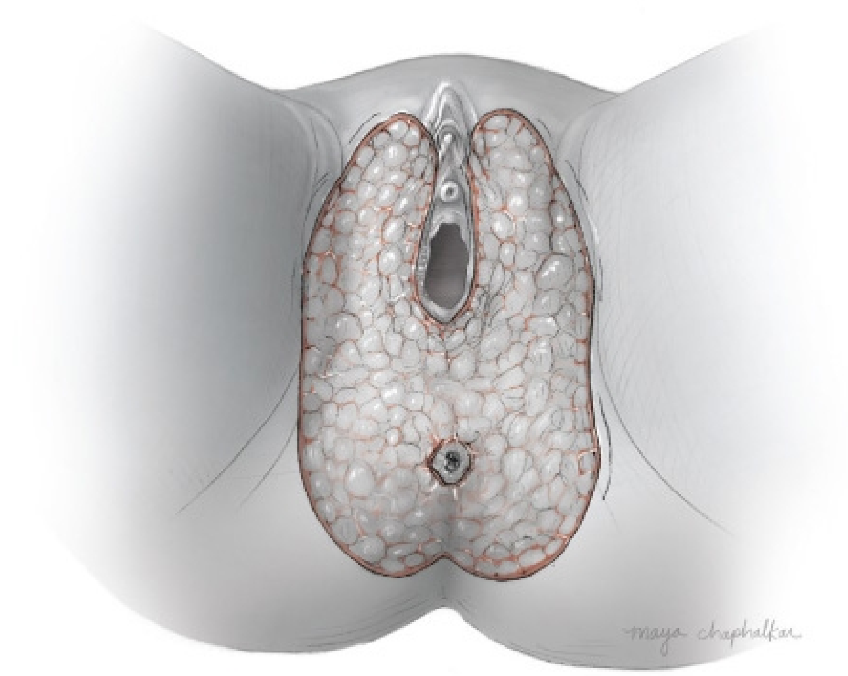
Intraoperative

Surgical Steps

1. **Anesthesia and Patient Positioning.** General or regional anesthesia is required. The patient will need to be positioned in dorsal lithotomy position with complete access to the vulva, upper thighs, and mons pubis. Sterile preparation of the lower abdomen, perineum, thighs, and vagina is performed, and a Foley catheter is placed. Infrequently, the buttock or hip will be selected as the STSG donor siteâ€”this will require additional repositioning.

2. **Evaluating the Surgical Defect.** After the vulvar resection has been completed and hemostasis is achieved, the wound is examined to confirm that primary closure is impossible (Fig. 43-26.1). The best graft or flap that will cover the defect adequately is determined.

FIGURE 43-26.1



Source: Schorge JO, Schaffer JI, Halvorson LM, Hoffman BL, Bradshaw KD, Cunningham FG: *Williams Gynecology*: http://www.accessmedicine.com

Large vulvar surgical defect.

4. **Split-Thickness Skin Graft (STSG).** An electrodermatome is required to harvest the graft from the donor site when performing a STSG (see Fig. 41-12.1). At a setting of 0.018 to 0.022 inches thick, normal epithelium is harvested from the donor site. The STSG is placed in a basin and moistened with saline. The donor site then is sprayed with thrombin, covered with a transparent film dressing (Tegaderm, 3M, St. Paul, MN), and wrapped firmly with gauze. The recipient site is irrigated with antibiotic solution, and hemostasis must be absolute. The graft then is held over the defect and cut to fit so that there is some overlap. Meticulous care is required to smooth graft wrinkles and avoid graft tension. Edges then are sutured to the skin with interrupted 3-0 nylon suture (Fig. 43-26.2). Moistened gauze or cotton balls are placed over the graft and covered with opened and fluffed gauze squares to provide light pressure. To create a stable dressing, a few ties usually are placed through the covering dressing and lateral to the graft site.

FIGURE 43-26.2

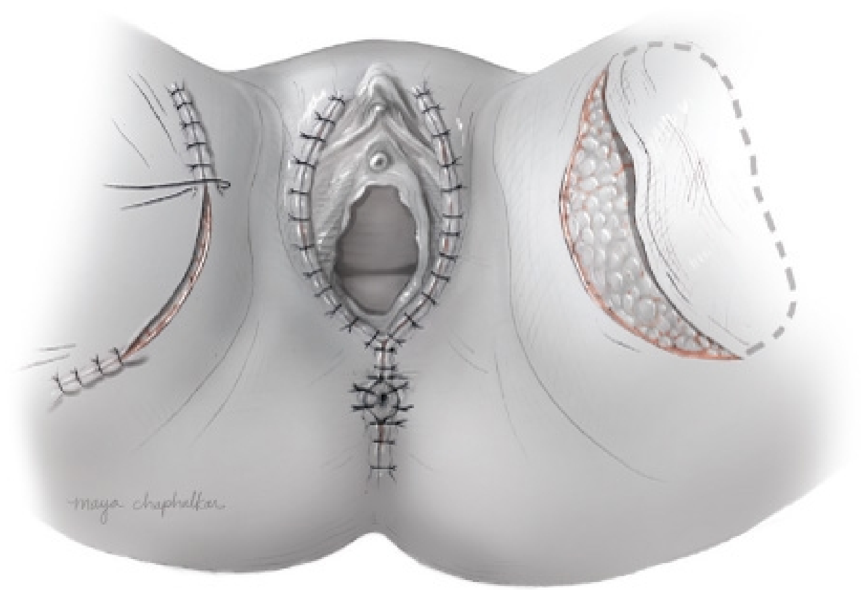
Split-thickness skin graft.

5. **Lateral Skin Transposition.** The skin lateral to the surgical defect is undermined extensively, and separate relaxing upper thigh skin incisions are made bilaterally. The resulting mobility of the vulvar skin should allow for a tension-free closure using interrupted vertical mattress sutures (Fig. 43-26.3). The relaxing incisions are separately undermined laterally and closed in similar fashion.

FIGURE 43-26.3



Source: Schorge JO, Schaffer JI, Halvorson LM, Hoffman BL, Bradshaw KD, Cunningham FG: *Williams Gynecology*: http://www.accessmedicine.com

Lateral skin transposition.

6. **Rhomboid Flaps.** A rhomboid is a four-sided parallelogram with unequal angles at its corners. When creating a rhomboid flap from adjacent tissue, a marking pen is used to draw all sides the same length as the short axis of the defect (*A-C* in Fig. 43-26.4). This minimizes wound tension and prevents necrosis. The diagonal *A-C* is continued in a straight line onto the adjacent vulvar skin lateral to the defect and marked so that the length of *AC = CE.* The remaining rhomboid sides are drawn in parallel.

   Incisions are made through the skin and into the subcutaneous fat. A flap is developed to include underlying fatty tissue and is mobilized medially to cover the surgical defect. Skin edges then are re-approximated with vertical mattress stitches using delayed-absorbable suture (Fig. 43-26.5). Typically, excess tissue at the corners requires trimming to provide a smooth contour. A suction drain is placed at the donor siteâ€"this area usually can be closed primarily without tension.

Rhomboid flap: closure.

Postoperative

Patients should be kept relatively immobile for the first 5 to 7 postoperative days to prevent tension on the reconstruction. A low-residue diet, diphenoxylate hydrochloride (Lomotil, Pfizer, New York, NY), or loperamide hydrochloride (Immodium, McNeil PPC, Fort Washington, PA) tablets will aid healing by delaying defecation and prevent straining (see Table 25-5). Thromboembolic prophylaxis should be continued until the patient is ambulatory (see Chap. 39, Prophylaxis Options).

During the first few days postoperatively, the wound should be examined frequently to identify signs of hematoma or infection. For STSGs, the transparent dressing may be removed from the donor site after about 7 days and an antibiotic ointment applied. For skin flaps, positioning changes or release of some sutures may be helpful if ischemia is noted at the margins. Suction drains are discontinued when output is less than 30 mL per 24 hours.

Women experience significant sexual dysfunction after vulvectomy. However, the extent of the surgery and need for reconstruction are less important than pre-existing depression and hypoactive sexual dysfunction. Accordingly, postoperative psychological counseling and treatment of depression may be particularly helpful (Green, 2000; Weijmar Schultz, 1990).
